It is not my intention to enter here into a description of the massive monuments which bear the Pelasgic or Cyclopian name; but it may be important to remark, that they consist of three distinct styles, which I should conceive to be referable to widely different periods of time. The first, which appears to be the most ancient, consists of walls formed of immense blocks of stone, roughly, if at all, hewn, generally of a square or oblong shape, put together with little care, and having the interstices filled up with stones of smaller dimensions. To this class may be referred the outer walls of *Tiryns*, the Pelasgic wall round the citadel of *Athens*, and a large part of the acropolis of *Mycenæ*. The second style includes those buildings which are constructed of enormous blocks of every imaginable shape, but most commonly pentagons and irregular rhomboids, and fitted together with the most scrupulous and beautiful exactitude. The galleries of *Tiryns*, some fragments which surround the hill of *Argos*, and others near *Arpino*, in the Southern Apennines, are the only specimens of this

class I have seen. The third and most modern division of Cyclopian architecture, is of a far more finished and somewhat less massive character; and the tomb of Agamemnon at Mycenæ, which forms the subject of this paper, is, as far as I am aware, the only instance of it extant.

The mystery which hangs over the origin of these massive structures, their singular appearance, and remote antiquity, all conspire to render them most fascinating objects of research. But at Mycenæ our interest was more peculiarly awakened by the celebrated *Gate of Lions*, the entrance to the Acropolis, and the one through which Agamemnon led his army to the siege of Troy. It is formed of two upright slabs of stone, 17 ft. high, and supporting an entablature of similar proportions, viz., 15 ft. long, 6½ ft. thick, and 4 ft. deep, hewn out of a single block. Resting upon this entablature is a triangular slab, 10 ft. high, containing in relief the figures of two lions, standing on their hind legs on each side of a pillar, the summit of which has been broken off. On the whole, it is a most magnificent gateway and on gazing on it, we are at a loss to conceive how, in those remote times, men could have acquired sufficient command of mechanical agents, to raise and place such enormous masses.

About 50 yards from the Gate, and outside the walls of the Acropolis, stands the immense mound, which forms the more immediate subject of these remarks. It is a large, round, conical hill, partly natural, partly artificial, and considerably lower on one side than on the other. On the side nearest to the Citadel an excavation has been made, which succeeded in laying bare the entrance or doorway, a structure of even more gigantic dimensions than the Gate of Lions. On entering this we come into a large vaulted chamber, inclining to the conical form, 50 ft. across at the base, and about 45 ft. high. Adjoining this is an interior chamber of square form, and smaller dimensions.

The chief peculiarity in this beautiful monument struck me as being the extreme neatness and regularity of the masonry. It contains 40 courses of hewn stone, all admirably fitted together, but without cement; and it is, I should think, quite as perfect a specimen of workmanship as could be produced at the present day.

Great doubt exists among the learned, as to *what* this monument really was—some calling it the Tomb of Agamemnon, and others the Treasury of Atreus. Dodwell and Dr. Clarke hold the former opinion, while Col. Leake and the generality of travellers are strenuous advocates of the latter. The only authorities on which we have to rely, are the description of Pausanias, and the plays of Sophocles and Euripides. From the former, it appears more than probable that the Treasury of Atreus was *within* the Citadel; and indeed we can scarcely conceive that any monarch who possessed a fortress as strong as that of Mycenæ, would deposit his treasures anywhere but within its walls. Now the monument in question is *outside* the fortifications, and therefore can scarcely be the Treasury of Atreus. Again; Pausanias places the Treasury near the spring *Persea*, which in no way corresponds to the position of this tumulus; for the only two rivulets to be found at Mycenæ rise 100 or 200 yards distant. Now we gather from different passages in the *Electra* of Euripides, as well as from that of Sophocles, that the tomb of Agamemnon *was* without the walls, (although Pausanias seems to indicate the contrary,) for Sophocles describes Orestes as visiting his father's sepulchre before he reached the gate of the Citadel; and in Euripides, when Orestes relates to Pylades his nocturnal visit to the tomb, it is expressly stated that he repaired thither without entering the walls. Now the tumulus in question *being* without the walls, and being also by far the largest to be found at Mycenæ, may fairly be conceived to belong to so celebrated a monarch; and to make assurance doubly sure, we learn from Sophocles that the sepulchre (*Τάφος*) of Agamemnon *was* a mound or barrow (*Κόλων*).

I have unfortunately neither the classic lore, nor the habits of antiquarian research, which could alone entitle me to form an independent opinion on this controverted point. Certainly from considerations above mentioned, I incline to Dr. Clarke's view of the subject. But the decision of the question is now of little moment; for whether

it be the sepulchre of the "King of Men" (*αρχὸς ἀνδρῶν*), or the Treasury of his father, the bones of the one and the treasures of the other have alike disappeared, and the Grecian shepherds, with their flocks and herds, are now the only inhabitants of this magnificent abode of grandeur and of gloom.

Passing over two barrows of unrivalled interest—that of the Athenians on the Plain of Marathon, and that of Achilles on the Plain of Troy, both of which have attracted so much attention from all travellers that it would be impossible for me to add anything to their descriptions—let us proceed to cast a short glance on the tomb of Alyattes, which is situated in the Plain of Troy.

Sardis is about two days' journey to the N.E. of Ephesus, from which place I set out to visit it. On the second day we passed Mount Tmolus, an extensive range which runs through Asia Minor, parallel to the two seas. These hills are extremely wide at their summit, and are covered with a rich soft grass, and ornamented by trees not inferior to the finest to be met with in our English parks. As we descended on the northern side, the Pactolus with its golden sands, now an insignificant streamlet, murmured gently by our path, sparkling with the dazzling beams of an Asiatic sun, from which even the rich foliage which hung over was unable entirely to protect it. A sudden turn at length brought us full upon the narrow glen which contains the Temple of Sardis, the only existing remnant, except the Acropolis, of the ancient city of Cræsus. The Temple is a most beautiful specimen of the Ionic order; and though two only of the columns are now erect, yet the others are lying around so little injured, that they might without much difficulty be replaced in their original position. It was curious to see our Turkish attendant sauntering amid the ruined fragments, and endeavouring, with all the honest politeness of his nation, to sympathize with us in our admiration of their beauties; though evidently extremely at a loss to conceive what should have induced us to come so far, merely to gaze upon the fallen columns and scattered friezes of an ancient temple.

But the description of Sardis, however beautiful or striking it may have been, is not our present object. About a mile beyond the Temple the glen opens into a wide plain, in which the cavalry of Lydia were defeated by the elephants of Cyrus. It is a truly oriental scene—the plain is of vast extent, and is surrounded by hills on all sides: at one extremity stand the Lake of Gyges and the renowned Tumulus of Alyattes. The sun was setting as we caught the first glimpse of this lovely landscape; its lurid rays shone over the still surface of the lake, the habitation of innumerable swans; the black canvas tents of the Turcomans (a wandering Asiatic horde) were scattered in profusion over the plain; camels and goats were feeding tranquilly around them; and the wild figures and uncouth dresses of the shepherds might be seen hurrying to and fro, to call the cattle to their nightly quarters.

The Gygian Lake is a wide piece of water, by the banks of which on the side nearest to the town, are great numbers of barrows or mounds of earth, and among them the Sepulchre of Alyattes stands pre-eminent. Herodotus, l. xciii, who probably lived about 450 B.C., speaks of it as being, next to the works of the Egyptians and Babylonians, the most stupendous monument existing. It was constructed, he says, upon a foundation of stone, and afterwards completed with earth. It was erected by three classes of the inhabitants of Sardis, viz., the merchants, the artificers, and the public women. At the summit of it were fixed five *termini*, or small pillars with inscriptions, declaring the proportion of work executed by each class of the artificers. Of these there is now no vestige. In the time of Herodotus this monument was somewhat more than three quarters of a mile in circumference at the base, but at present it is considerably less. Unfortunately he does not mention its height, nor had I, when there, the means of measuring it, but it could not fall far short of 200 ft. Several attempts have been made to effect an entrance into the monument, under the idea that treasures would be found there; but hitherto little more has been done than to scratch the surface; and the interior construction of one of the most ancient sepulchres in the world, (B.C. 560,) is still a secret.

Though there is less of mystery, there is scarcely less of interest, connected with this enormous barrow, than with the one at Mycenæ. We know beyond all doubt, that it is the monument of Alyattes, the father of Cræsus, and the king of Lydia. We know that it was erected by order of the wealthiest monarch of Asia, that it was described by Herodotus, and that it must have been visited by Solon; and there is surely enough of magic in these associations to awaken our warmest sympathies for this mighty relic of a people whose fertile empire is now a desert, and whose once formidable name is almost lost in the remoteness of past time.

DESCRIPTION OF THE CYMAGRAPH FOR COPYING MOULDINGS.

By R. WILLIS, M.A., F.R.S., Jacksonian Professor in the University of Cambridge, &c.

(With an Engraving, Plate IX.)

THE purpose for which this instrument is constructed is to obtain exact drawings of the profiles of existing mouldings. The importance of doing this is well known; but the methods hitherto employed have appeared to me susceptible of improvement. The oldest and most usual is to measure a sufficient number of ordinates and their distances, and thus to lay down the mouldings by points. When the exact form is required, lead tape has been employed, or clay; but the best method of all is to lay the bed of the stone upon which the mouldings are carved upon the paper, and trace the outline, or else to make a saw cut transverse to the mouldings (or through a joint) and introduce paper into this cut, upon which the section of the moulding may be traced. But these latter plans, excellent as they are, can only be employed in dealing with ruins, neglected buildings, or buildings under repair. A few years ago I contrived an instrument which consisted of little more than the stylus of the present one, and which I then presented to the Institute of British Architects under the name of a Cymagraph. But I found it too troublesome to use with the necessary precision, and yet so useful that I have been induced to fit up a more complete and commodious machine, which is represented in the annexed figures, and to which I shall venture to apply the same name, Cymagraph. This was exhibited at a meeting of the Institute of British Architects, on May 16 last, and the instrument itself deposited in the hands of the secretary for the inspection of any person who might wish to copy it. The following description will, I hope, prove sufficient for the same purpose.

The instrument, when folded up, is 5½ in. by 11½ in. and 1½ in. thick, and will travel in a carpet bag without injury.

Fig. 1 is a plan of the instrument in its working state, applied against a Gothic rib for the purpose of copying the mouldings.

Fig. 2 is a side view of the instrument corresponding to Fig. 1.

Fig. 3 a plan of the lower side, in which the cymagraph is represented as detached from the board, and folded into its place for convenience of carriage.

The principal piece of the machine is the stylus ABC, of which the portion AB is straight and BC curved. AB is mounted in a frame or carriage, having a pointed screw at A, and a collar at B, so that the stylus is capable of revolving, and the curved portion BC, which is nearly in the form of a semicircle, is terminated by a point at C, which must be exactly situated in the axis of rotation of the stylus, so that during the rotation of the latter the position of this point may remain invariable with respect to it and to its carriage.

A button D, either of hard wood or of brass, with a milled edge, is fixed to the stylus, and serves both to guide it in its motion along the surface of the mouldings and to turn it round its axis as required. The carriage in which the stylus is mounted has also a pencil holder E fixed to it.

If now the carriage with its stylus be moved parallel to itself over the surface of a drawing board, it is clear that any given point of the carriage will describe precisely the same path as the point of the stylus does, and since the pencil is attached to the carriage, this will also be true for it; so that if the tracing point C of the stylus be made to pass transversely across a series of mouldings, and the point be at the same time kept always in contact with their surface, the pencil will simultaneously describe upon the paper the exact form of the section of these mouldings of the same size as the original.

But the surfaces of mouldings are inflected in various directions to the right and to the left, and the tracing point of the stylus must therefore be capable of following such changes of direction. This it is enabled to do by its curved form combined with its power of rotation about its axis; for by turning it, it can be applied at various degrees of inclination, either to the right or left side of a moulded surface, as the form of the latter may require. And as the rotation has been shown not to affect the actual position of the tracing point C with respect to the carriage, so neither can it affect the truth of the section drawn by the pencil.

For example, at C the tracing point is applied to the right of the stone surface, but at X on the opposite side of the rib it is applied to the left of that surface, and is also turned into a different angular position to enable it to enter the hollow. But in passing from X to Y it must be gradually turned into the position shown by the dotted lines, to enable it to clear the projection at Z. In fact, during its progress across a rib of this kind, the point must be carefully watched, and the stylus turned into the best angular position that the momentary form of the moulding requires.

I have said that the carriage of the stylus is always to move parallel to itself, and will now describe the means by which this is compelled.

The base of the machine is a drawing board of mahogany FG ($\frac{3}{4}$ in. thick), 10 $\frac{1}{2}$ in. by 11 $\frac{1}{2}$ in., and made to fold in the middle like a book, for the convenience of carriage. When in use it is kept open by a button R on the lower surface. The carriage is guided by a parallel motion somewhat resembling a double parallel ruler, but the proportion of whose jointed arms are altered to suit the different circumstances of its employment.

A plate H is secured to the board by a button-headed screw, K, having a milled headed nut below at L. As K merely enters a notch in the plate H, a single turn to right or left of this nut L is sufficient to detach or fix the plate, together with the instrument, while the slip of metal M, screwed to the board, serves to keep the plate in its proper position.

Two arms NN of equal length are jointed to the extremities of H, and also to an arm P of the same length as H; consequently P will be parallel to H in all positions. Two other arms QQ, also of equal length, are jointed at one end to the arm P, and at the other to the carriage of the stylus, so that the latter will be parallel to P in all positions, and consequently to H. This arrangement enables the carriage to move freely and steadily from one side of the board to the other, and over every part occupied by the paper, and at the same time keeps it always parallel to the plate H. The paper TS, upon which the mouldings are to be copied, is secured to the board by a pair of spring catches V, W, of which the last is placed near the corner S of the paper, to prevent the latter from being caught and turned up by the arm N of the instrument during its motion.

It is absolutely necessary that the board of the instrument should be held steadily, in the same position, against the mouldings during the process of tracing. The two retaining pieces *a*, *b*, *d*, are provided for this purpose; these are attached to the lower side of the board by thumb-screws, *e*, *f*. In Fig. 3 they are shown in the position requisite for closing the instrument, but in Fig. 1 they are in the position for use. When the thumb screws are relaxed, either of the retaining pieces may be drawn out, and turned to the right or left so as to touch some convenient projection of the moulded surface, and thus when clamped fast, to retain the instrument in the same position so long as it is pressed into contact with the mouldings.

This adjustment of the retaining pieces must always be made pre-

viously to taking the profile of any mouldings; the board must then be grasped in the left hand at O, and held firmly against the mouldings. The button at D is managed by the right hand, which will be found sufficient as well to guide and turn the point of the stylus as to keep the pencil in contact with the paper, and to raise it off the paper when necessary, which the elasticity of the parallel motion will allow of easily.

Fig. 4 is a section of the edge of the board at W, to show the form of the paper springs. These, which are also seen at *h*, *h*, Fig. 3, are screwed to the lower side of the board in sunk recesses, and are released from the paper by pressing them at *k*. When the plate H, with the parallel motion and carriage, are detached from the board, they may be deposited in a recess sunk for the purpose on the lower surface, as shown at *l*, *m*; the button R is then to be turned into the position shown by the dotted lines, and the board may be folded together, and secured by a hook in front. The recess at *n* receives the stylus, and those at *s*, *s*, *s*, receive the milled nuts *e*, *f*, L, respectively.

When a series of mouldings are to be copied which exceed the limits of the paper, they must be taken piecemeal, as shown at Fig. 5. This figure shows how the entire rib of Fig. 1 may be represented, which rib is too large to be entirely comprehended within the boundaries of the paper. In this and similar cases it is better to apply the instrument against the right and left faces of the rib in succession. In the first operation the mouldings from *o* to *p* (Fig. 1) will be taken, and in the next operation those from *q* to *v* (the same letters are employed in Figs 1 and 5).

Care being taken always to draw an overlapping portion of the mouldings in the successive drawings as in this case from *q* to *p*, there will be no difficulty in joining the separate pieces into one continuous line by tracing them on a larger sheet.

A small black-lead pencil and common paper may be used for the purposes of this machine, but as the point is very liable to break and become troublesome, I find it much more convenient to employ the *metallic* paper, which is prepared by Messrs. Harwood, 26, Fenchurch Street, and requires only a brass or other metallic point instead of black lead. Besides this advantage, the trace is indelible. The paper for the instrument should be cut to the proper size, and carried in a portfolio. By a somewhat different arrangement of the instrument, the paper might be made to remain always in its place on the drawing board in the form known by the name of a *block*, from which the sheets are to be detached as fast as the drawings are made. This would increase the size of the machine, however, by making it exactly as large as the paper, and the folding hinge would be placed in a direction transverse to that which it occupies in the present design.

This instrument requires no great accuracy of workmanship. The two essential points upon which the precision of its action depends are, 1st, that every pair of arms NN, QQ, of which the parallel motion consists shall have exactly the same distance between their joint holes. This is easily secured by drilling them all separately, from a pattern arm made previously. Similarly the holes in the plates H, P, and the carriage, must be at the same distance respectively. 2nd, that the point of the stylus shall be in the axis of rotation. This is also easily effected, and is as easily verified at any moment by twirling the stylus in its carriage opposite to a fixed point.

The parallel motion may be made of thin slips of sheet iron rivetted together, but better of sheet steel. The hinges of the board must be so placed that when it is closed or folded, there may be room between its inside surfaces for the retaining plates *e*, *f* and the button R, which must be made all of sheet iron or brass of the same thickness.

The length which I have given to the arms of the parallel motion, is just sufficient to allow the pencil to travel over the board. The limit of the motion to the right will be found to be that the arms QQ will come into contact, and thus prevent farther motion in that direction; and similarly the limit to the left will be the contact of the arms NN. If the size of the instrument is increased, the same proportions must be preserved between the arms and board.

THEMÆ OF ANCIENT ROME.

ON THE THERMÆ OF ANCIENT ROME.

(With an Engraving, Plate X.)

Extracted from a Paper read by the REV. RICHARD BURGESS, B.D.
Honorary Member, at the Royal Institute of British Architects on
Monday, 30th May, 1842.

* * * If, as I have before observed, we learn from the study of temples much of the religious rites of antiquity, if from the Basilicas something of the mode of administering justice, if from theatres and amphitheatres the public sports and pastimes, if from circuses and stadia open air exercises and recreations, all which I have attempted on former occasions to make out, with a little topography by way of light reading!—from the Thermæ or public baths of Rome we may learn something of that “*luxuria scavior armis*” which finally overcame the courage of the Quirites and the modesty of the Roman nations.

It will not answer any purpose except that of tiring my audience, to investigate the state of swimming and bathing in ancient Greece; and unless Scipio could be shown to have been particularly hostile to ablutions, I do not see why classical writers should make it such a wonder that he had a bath. Seneca saw the remains of Scipio's bath at his villa at Liternum, which he calls a “*balneolum angustum tenebricosum*,” which may be translated ‘the black hole of Calcutta, filled with hot water.’ “But who,” the moral philosopher asks, (after having described the darkness of Seneca's *blattarium*), “would endure to bathe in such a place now? In short,” he adds, “we have got to that pitch of refinement that we cannot even put our foot upon anything but gems.” Leaving, however, the Greeks to bathe in the sources of the Xanthus, and the Romans of the republic to lave their hardy limbs in the waters of old Tiber, we will proceed at once to the period when the luxury of the warm bath began to be publicly enjoyed at Rome. I shall first give you a *catalogue raisonnée* of the thermæ from the Augustan age to the reign of Constantine, and then proceed, with the help of our architectural illustrations, to describe the different parts and uses of the edifice, noticing as I go along the variety of occupations for which the thermæ were destined.

Agrippa was the first to teach the Roman people the indulgence of the warm bath. The thermæ which he erected in the Campus Martius were bequeathed to the public, and they were embellished, according to Pliny, with various works of art. Amongst the statues was the bronze youth in the act of undressing, called the *Apoxyomenus*, a work of Lysippus, of surpassing beauty. Some remains of the thermæ of Agrippa still exist immediately behind the Pantheon, and extending, with interruptions, to the large fragment of a vault called, from its resemblance to a crown, the *Asco della Ciambella*. Those baths had only the *corpus internum*; and except the *sudatorium laconicum* mentioned by Dion Cassius, we are unable to trace by the vestiges that remain, any of the usual compartments of a thermæ establishment. It will occur to many who now hear me, that the Pantheon, when stripped of the inimitable portico, and opened at the large tribune facing the entrance, would be reduced to nothing more than a principal hall belonging to the baths, very much resembling, both in form and position, the round room to which I shall have to refer in the thermæ of Caracalla (see ground plan of Pantheon). I believe it must be allowed (however shocking to our classical tastes and feelings,) that the portico of the Pantheon was an afterthought, and that the magnificent cupola was originally intended for the large hall of Agrippa's thermæ. Of the baths of Nero and Vespasian we know nothing, except that the former, *Balnea Neroniana*, are mentioned by a poet of the fifth century as being adjacent to the thermæ of Agrippa.

The next great baths erected at Rome were by Titus: they were built over the ruins of Nero's overgrown palace, and their vast remains still cover a good portion of the Esquiline Hill. The well-known plans and illustrations of De Romanis will render any farther description here superfluous (see plan). I may, however, observe that, taking a measurement of the thermæ of Titus, and guided by the indubitable vestiges remaining in the several vineyards and lanes around, the whole

space occupied by the buildings must have been three-quarters of a mile in circumference. I am not aware that any description or any account whatever has reached us of those immense thermæ: the ruins themselves are the mute historians of what they once were, and it is from the subterraneous vaults containing the celebrated arabesque paintings that we learn that the house of Macenas, embodied in the palace of Nero, formed the foundations of the area on which the thermæ Titianæ were erected. Those baths were built at about the same period as the Flavian amphitheatre: the reservoir, called the *sette sale*, for supplying the water, is still to be seen.

If we consider the thermæ of Agrippa and balnea Neroniana as parts of the same establishment, we may equally annex the thermæ Trajanæ to those of Titus, making *two* large public baths; and except the balnea and lavacra of a more private kind, these were all that serve to indicate the progress of luxury during the reign of the twelve Cæsars and their two immediate successors, which brings us to the 120th year of the vulgar era. Considerable remains of the thermæ of Trajan (which were probably begun by Domitian to complete the work of his brother,) are to be seen beneath the church of S. Martino ai Monti. We are indebted to ecclesiastical writers for a notice of these baths: they were the scene of two councils, in which the heresies of the third and fourth centuries were condemned; and although they are to be considered as a continuation of Titus' works, yet they retained in later ages a distinct appellation. The thermæ of Hadrian were a still further addition, or perhaps the completion and embellishment of the works of his predecessors might cause the name of that imperial architect to be inscribed on the walls. Two statues of the young Antinous were found amongst the ruins; and perhaps this circumstance has chiefly prompted antiquaries (who sometimes snatch at shadows,) to put Hadrian's name into the list of builders of baths. If, however, the thermæ of Titus were begun by him, carried on by Domitian, and achieved by Trajan and Hadrian, the work must have been in progress from first to last for about 30 years. If we except the thermæ publicæ, the position and extent of which have not been ascertained, we go through the second century, including the golden age of the Antonines, without any further increase of those luxurious establishments. At this period (dating from the reign of Commodus,) historians generally date the period of the decline of the Roman empire; and from this same period the great increase of thermæ began. It was during the third century that those prodigious edifices were reared whose remains are to occupy our attention this evening. The first are the Thermæ Antonianæ, built in the reign of Caracalla, and finished by Alexander Severus. This immense structure was begun in the year 205 or 206, and was finished with the exception of some outworks added by the successors of Caracalla, before the year 217. In the excavation made by the Conte Velo di Vicenza in 1826, a fragment of marble was turned up, on which were read in ill-formed letters the names of Albinus and Emilianus. As this fragment of marble appears to be unworked, one would conclude that it is as it came from the quarries, where it was not unusual to scratch the names of the consuls for the year upon the surface of the blocks. We are thus enabled to say that in the year 206, when the two consuls named were in office, the materials were preparing for the erection of the thermæ near the via Appia. They were situated near a valley which divides the Aventine mount, and in which formerly were the Piscina Publica. It will be seen, by reference to the plan, that they were nearly a mile in circumference, including the exterior porticos, and it may be imagined what the riches of this fabric were, from the profusion of marble and the exquisite works of art which at different periods have been found; 1600 seats of polished marble furnished the interior of the apartments, and the Cella Solearis, to which we shall shortly recur, was the wonder and admiration of all architects. The ancient authors have left us scarcely any description of those baths, but they almost seem at a loss for words to express the splendour of the building. The seven-leagued word of “*magnificentissimas*” and “*thermæ eximæ*” are found in Spartian. Eutropius calls them an “*opus egregium*,” and when we find vestiges of tessellated pavement on the topmost stairs, where the

attendants had their lodgings, we may judge what the rooms below must have been, for the reception of emperors, senators, knights, and the Roman people. There were also in this same region some thermæ erected by the emperor Decius about the middle of the third century. We are also made aware of some thermæ of Philip by the fragment of an inscription, and we know from Vopiscus that Aurelian built baths in the regions beyond the Tyber. But the next great wonder were the prodigious thermæ of Diocletian, erected towards the close of the third century. Scarcely any mention of this stupendous fabric is to be found in any of the ancient writers whose works are extant. The story that forty thousand Christians were made to work like slaves in rearing the building, rests upon very slender authority; but if it were so, they might have been consoled with the reflection that they were only aiding to erect a Christian church, for one of the most splendid basilicas of Rome is now formed out of the ruins. We shall shortly recur to the remains of those baths when we come to description. The next and last edifice erected in ancient Rome for this purpose were the thermæ of Constantine, probably about the year 325. Considerable remains of these exist on the Quirinate Hill, adjoining the Colonna Gardens: Sextus Aurelius says they were not inferior to the other. The two colossal equestrian statues now on the Monte Cavallo, the bas-reliefs and busts, as well as the fresco paintings kept in the Ruspigliosi Palace, all came, as it is most probable, from those ruins. The three statues of Constantine and his sons (two of which now stand on the balustrade of the Campidoglio), and above all the inscription which relates that a præfect restored those baths to their pristine splendour, prove that we are right in identifying those ruins with the name of Thermæ Constantinianæ. The remains now visible are used for hay lofts, and are not sufficient to enable an ordinary observer to form any idea of their plan or extent. Nevertheless the creative genius of Palladio and Serlio has attempted the task of restoration, and it is not for me to cope with such high authorities, of whom, as well as of the baths they illustrate, it may be said to their immortal honour, *stant nominis umbræ*.

We have now run through the catalogue of thermæ which were erected at Rome during the first three centuries of the Christian era, and there is no reason to suppose they were not *all* existing when Constantine added those we have just mentioned. Publius Victor, in his reginary or catalogue of public buildings, made about the year 360, enumerates all the great thermæ we have mentioned as then existing; and under the same head (together with Lavacra) reckons up a total of fourscore. Besides these, there were the balnea in private houses, the nymphæa and lacus in gardens, and the aquæ sanatarie, more or less used for bathing; and such was the accommodation for the luxury of cleanliness, that not an inhabitant of Rome, unless he decidedly preferred it, need have continued unwashed, for in the public establishments a bath might be had for the smallest piece of money coined at Rome*. But our wonder will be increased at the magnificent luxury of the Romans, when we have made ourselves acquainted with the different parts and uses of a thermæ establishment, which I now propose, according to my slender means, to point out to you.

DESCRIPTION.

All the thermæ, as far as we have the means of ascertaining, had the same aspect, and with very little variation in the distribution of their parts. It will be seen by reference to the plan of ancient Rome, that the three great fabrics of that description, which in part remain, have had their principal elevations towards the south-west: by this arrangement they secured the means of providing summer and winter apartments, as they did in their large villas. The space occupied by the thermæ was nearly a square: in the case of Caracalla's each side measured 1100 feet; of Diocletian's about the same; of Titus' something less. Attached to each was a castellum aquæ or reservoir, divided into compartments, and supplied by an aqueduct, so that an

abundance of water was always at hand for the purposes of the establishment. In Diocletian's and Titus' baths those reservoirs were detached from the main building; in Caracalla's it served as the back of the theatridium, while the immense thickness of the walls prevented all inconveniences. On each side of the theatridium, where the spectators sat to view the exercises in the arena, was a palæstra, (K) which, according to Vitruvius, ought to be a peristyle, either square or oblong. In these, gymnastic exercises were performed in the winter months, and on either side of those were rooms destined for the attendants or balneatores; those at the end (O) have upper stories, and the stairs cut in the walls are still to be traced. The same disposition may be observed in the baths of Diocletian, and something similar, though much less perfect, in the Thermæ Titianæ. I have said that the place in front of the theatridium was the arena for exercises in the open air: the ample space lying between that and the principal elevation was the grand xystus (Q) or pleasure-ground. The xysta, Vitruvius says, ought to be made so that, between the porticos, there may be groves and rows of plane trees. Walks, he adds, (ambulationes) should be laid out among the trees, and places for repose (stationes) should be made of opus signinum. A similar space, though inferior, lies behind the north-west elevation (F), and this I take to have been the minor xystus, where the lower orders of the people were permitted to have free access, and might extend their perambulations on each side of the nine peristyles. Vitruvius speaks of xysta in the plural number, and I think by comparing the plans of the other thermæ, it is evident that each was furnished with a major and minor xystus, observing that distinction of classes for which equality men are in all ages so remarkable, but which we can adjust without any odious comparisons, by having our xystus major at the end of Picadilly, and our xystus minor somewhere about the Tower Hamlets! But to proceed with our outworks: it is generally supposed that the two large hemicyclia, one of which remains almost entire as to its ground plan, were added by Helio-gabalus. They contained, first a palæstra (K), communicating with rooms (L) or scholæ where, in all probability, philosophers delivered public lectures, and with some square compartments (J), which we would designate academies for holding discussions. The open walks (N) are Vitruvius' hypæthræ, and they communicate with the covered Ambulachra, which were not unlike the cloisters of a monastery. Here the students and philosophers could take their exercise in undisturbed meditation, and repass at pleasure into the long hypæthræ ambulationes (H) which, according to the Vitruvian precepts, ought to join the xystus. In other thermæ the two sides of the square wanted those magnificent hemicyclia, and had more of the exedræ, like (G); they were furnished with seats for *conversazioni*; in Diocletian's baths such recesses were numerous. The fourth side of the exterior works, turned towards the via Appia, presented a splendid elevation, as may be well conceived from the illustration of M. Blouet. There are sufficient indications of this lower series of compartments having been used for baths, and I rather think that these were dedicated to the use of the common people, who might pass from them into the minor xystus. There were not less than fifty separate baths, each with its ante-room (C), where the bathers might undress, and from whence they might ascend by staircases to the higher parts of the building, or pass into the portico, which continued the whole length of the front. The elevation consisted in two rows of arches supported by columns, and surmounted by a balustrade ornamented with statues. The spectator, in viewing this front from the via Nova, (a street made when the thermæ were erected,) saw the stately trees of the xystus waving their luxurious foliage above the balustrade, and the dome which covered the pinacotheca rising majestically over the whole; and after approaching the vestibule (I) in the middle of the elevation he ascended into the xystus, and betook himself, as we shall now do in imagination, to the interior of the fabric.

It will be remarked, by a slight reference to our ground plan, that there are duplicates of all the rooms and peristylia, and that the middle space is occupied principally by three large compartments, the first (J') girt with the spacious hypæthræ (H), has been a circular

* ——— Dum tu quadrante lavatnm,
Rex ibis. Horat. Sat. i. 3.

room not unlike the Pantheon if stripped of its portico. This is supposed to be the *caldarium*, and being exposed to the sun, received much of its heat therefrom; to which the hypocaustum or place for heating water being adjacent, or underneath, gave additional warmth; in the midst was a circular reservoir, in which the bathers took their exercise together, the spectators, leaning on a barrier, were admitted to the suffocating sight. Any one who has seen the large baths in Turkey may form a correct notion of a *caldarium*. I allude now especially to the baths at Brousa, in Bythinia, at the foot of Mount Olympus, where I have seen this process of hot bathing, and where the Turks seem to enjoy swimming in water heated to a degree which would certainly boil a Christian or skin a Jew. After the process of scalding, it must have been grateful to the sensations to pass back again into the next room (I'), which was the *tepidarium*; in this also there was room for swimming about, and after this (*in the returning process*) the bathers passed into the large room, which is the second of the three mentioned, and which was the *cella tepidaria*; here in four recesses were deep and ample basins (G'), discovered in the excavations of 1826 to have been lined with marble, with the steps for descending into them existing; in the centre of each side were two immense circular basins called *Baptisteria*, and which are probably those now standing in the Piazza Farnese; this spacious apartment (F) with the rooms (H) at each end, measures 300 feet by 100, and the centre portion of it was supported by eight immense columns of granite, and must have been the most imposing saloon in the whole establishment. Taken in its whole extent, we conceive this to have been the *pinacotheca*, which the ample room now formed into the church of Sta. Maria degli Angioli, at Diocletian's baths, resembles. The third great compartment no one doubts was used as the *natatio* or cold swimming bath, called also the *frigidarium*, and sometimes *piscina*, because originally a large basin of cold water or a lake, where fish were kept, was so called; this too was supported by 8 columns, not inferior to those of the *pinacotheca*. At each end were the *vestibula* (Y), and the *Apodyteria* (Q'), and the rooms (A') where the *Capsarii* took care of the clothes, and the corresponding places B' C', where the *Aliptæ* and *Unguentarii* were ready to anoint and perfume the bathers, and the rooms D' called *Diætæ*, where they might have refreshments. By this arrangement, the bathers who desired to go through the whole process of a purification, might pass from the cold *natatio* facing the north to the *caldarium* facing the south, and return again by the same gradations of heat and perspiration, until they were ready for a repast or a repose, or a conversation in some of the numerous apartments. Such were the rooms (R' T') and perhaps others that might be reached by ascending to the second story; * now either the large room (J') or (F') must have been that famous *cella solearis* mentioned by Spartan, and as the middle room, holding the most prominent place in the whole plan, appears to unite all the properties necessary to meet the description, I have always been of opinion (before I had the satisfaction of finding M. Blouet agree with me) that the *pinacotheca* was the *cella solearis*; I do not think it necessary, however, to stand out for the heat of the sun, for antiquaries yet differ upon the word *solearis*, and the room, as far as the epithet goes, might either be called from the sun or from the lacing of a slipper; the remarkable feature of this *cella solearis* was the working of the roof; it appears to have been fretted or cancellated by copper lacing over a vast extent of space, in such a way as to render both its design and execution a matter of astonishment to artists; if the large central room which I have designated the *pinacotheca* was the *cella solearis*, then its magnificence would be increased by the works of art which were placed in it, for such rooms in the public *thermæ* became as many national galleries where paintings were deposited (as the word *pinacotheca* implies), and other specimens of art which the authors thought fit to expose. The space was so ample that it was not necessary to make previous application for a good place, and the admission being gratui-

tous, the connoisseurs paid more than one visit, and found out the good picture or statue in the most obscure places. Our attention is yet to be called to the two large open *peristyles* (U') in which the athletic exercises were performed, as the Mosaic pavement opened in 1826 indicated, for in the semicircular recesses (P') were represented full figures of *Discobuli*, some with their names written near them, others with the wreath of conquest in their hands. The *hemicyclia* (P') were used for the visitors of the sports, and the separate divisions (V') were probably schools or *ephebia*, where the youthful arms were practised in manly exercises. We have now only to finish the principal façade of the *xystus*. On each side of the *caldarium* (or circular room in the middle) is a comparatively small basin (K), and these I take to be the *sudatoria*, one for the men and another for the women. By a passage from these we enter into two square rooms, which are suitable for the *vestiaria*, and may be considered as the *apodyteria* for this more dignified part of the baths. The rooms M' and N' may fairly be assigned for *gymnasia* in fine weather; the corner apartments (N') are open on two sides, and lead into the *xystus*; to complete our idea of this once splendid building, we may look at the restored elevation of this façade by M. Blouet, which, after what has been said, we can hardly believe to be over-wrought or exaggerated in ornament.

I may not lengthen this paper by attempting to speak of the construction and materials of this ancient edifice; the quantity and quality of its decorations may be inferred from the noble specimens of art that have come out of its ruins; the Farnese Hercules, the Glycon, the Bull, the Torso Belvedere, the Atreus, are too well known to need repetition. The treasures found and carried away by the nephew of Pope Paul III. were enough to have formed an interesting museum of antiquities; the Flora, the two Gladiators, and a quantity of busts were among them. The granite column now standing at Florence attests the magnitude of the *pinacotheca* from whence it was taken; and yet all we know is perhaps but a fraction of the rich art with which those *thermæ* were embellished. When we consider the immense provision made for bathing in ancient Rome (for there were seven or eight great *thermæ* at one time existing), the practice must have been diffused throughout the whole population. As early as the Augustus, a poor man might wash for a farthing, and little boys (Juvenal intimates) paid nothing. But the practice, which at first was wholesome and of public utility, afterwards degenerated into effeminacy and indolence. The Emperors promoted the abuse of the bath by their example; Hadrian bathed in public with the lowest of the people. But it is a consolation, to know that those splendid edifices were not erected solely for the sordid purpose of bathing; by reference to our ground plans we shall see that but a portion of the whole *thermæ* was dedicated to that object; we may leave the motley throng in the *frigidarium*, pass by the half naked groups in the *cella tepidaria*, and say nothing about the delights of the *sudatorium*, or the boiling process of the *caldarium*; the filthy and effeminate we may enclose within the limits of the three large centre rooms; but all the rest of the space was dedicated to nobler and more manly purposes. The whole must have presented an animated scene, and the magnificent display of works of art appears to have compensated in some degree for the disgusting exhibition of works of nature. In the *peristyles* were the competitors for a laurel crown exerting their muscular strength, while poets and philosophers sat looking on in the recesses of the *exhedræ*; there a public orator delights an intellectual audience with the flowers of rhetoric; in the walks of the *xystus* wandered in groups the sons of Apollo, while the notes of the lyre resounded from behind some shady plane tree; parading in the *hypæthræ* were senators and politicians, and in the more retired *ambulachra* the students of Plato's or Aristotle's philosophy; in front of the *theatridium* the foot race was run, and the applause which saluted the man who won, rung through the stately arches of the adjoining *hemicyclia*; in the terraces of the upper story were companies of idle but witty spectators, looking down upon the passengers moving along the Via Appia, or espying from afar the approach of a governor returning from his province. A thousand occupations of pleasure and

* M. Blouet, however, designates the room (R') *sudatorium*, applying some directions of Vitruvius a little too vaguely.

recreation were carried on within the walls of the lofty apartments, which were covered with all the variety of colours and costly material, where the Egyptian granite was incrustated with the green, yellow and red marbles of Numidia. In the midst of this splendour might have been seen a swarm of dirty and ragged plebeians criticising the painting and statues of the pinacotheca, and although they indulged in gross and vulgar sensuality, could display a taste in works of art which our modern populace might envy. In winter as well as in summer those places of public resort were open; the soft climate of Rome required no fire to warm the room with a southern aspect, and the fountains which played in every direction refreshed the very air in the hottest season. This description is not only applicable to the thermæ of Caracalla, but also to the others whose ruins still exist, and cover almost an equal space. Indeed, if we may credit Olympiodorus, the baths of Diocletian had more than 3000 seats of polished marble. Nor have we yet mentioned all the apartments and their uses which a thermæ establishment contained; we have assigned no place for the conisterium, where the athletæ were sprinkled with dust, that the antagonist might hold him the faster; no place for the elæotherium where he was besmeared with oil, that the hold might be slippery; there was the spheristerium or tennis court; the bibliothecæ, the corycæa, the musea, must all find a place; but I have not attempted to fasten a name upon every compartment, just for the sake of filling up the plan. Let it suffice to have enumerated the parts and uses of a thermæ, and with the help of other men's labours to have illustrated one of the principal causes of the decay of the empire. It is thus, gentlemen, that we learn, from the labours of the antiquary and the architect, what the historian has passed over in silence, and we are enabled, with these plans of the ancient thermæ before us, to account for the facts which the historian has recorded, viz. that the valour of Rome sunk ingloriously before the vigorous arm of the barbarian. It was when Vitiges, the king of the Goths, cut off the supplies of water in the fifth century, that the thermæ began to be deserted, but not before they had been one of the most powerful causes in bringing those Goths to the walls of Rome. If a society for the suppression of vice had arisen in the age of the Antonines, the plague might have been stayed; but in the absence of moral and legal restraint, vice was promoted and activity of body destroyed; and it might have been said with truth of the motley crowd in a thermæ,

"Non his juvenus orta parentibus
Infecit æquor sanguine Punico."

But in making some practical application of this subject, I would observe, in conclusion, that it does not follow, if we could have some such public establishments now, that the same evils would arise; with our experience of past ages, and with that leaven of morality which the influence of a pure religion has introduced, it might be possible for us to adopt all the advantages of the thermæ without their mischief; their cleanliness and health-promoting exercise without their effeminacy, their means of recreation without their idleness, their useful resources without their foolish luxury.

"Think'st thou there is no tyranny but that
Of blood and chains? the despotism of vice,
The weakness and the wickedness of luxury,
The negligence, the apathy, the evils
Of sensual sloth, produce ten thousand tyrants,
Whose delegated cruelty surpasses
The worst acts of one energetic master."

To this the thermæ of Rome bear witness, and therefore our thermæ may not resemble those. * * *

Iron Wire Bridge.—It is strange that the plan of making bridges of iron wire, so successfully adopted in Switzerland, France, and elsewhere abroad, should not yet have found favour enough in England to be fairly tried on the large scale; the noble bridge at Freyburg, in Switzerland, is 301 feet wider than the Menai Bridge, and though it consists of one span, it is at least equally strong, and cost only a fifth part of the money. The wire bridge of Freyburg is 870 English feet span; that of Menai 569. The Menai bridge cost 120,000*l.*, that of Freyburg, 25,000*l.*—*Patchwork, by Captain Basil Hall.*

ON THE PRESENT STATE OF COLOGNE CATHEDRAL, AND ITS PROPOSED COMPLETION.

"They dreamt not of a perishable home,
Who thus could build." —

THE cathedral of Cologne, if completed as proposed by the powerful mind which designed it, would probably be one of the most wonderful and beautiful monuments of the skill of man in the whole world;—its enormous size, the elegance of the details, its completeness as a whole, would alike strike the beholder as unequalled and surprising. Cologne, although as Coleridge says,

"———— a town of monks and bones.
And pavements fanged with murderous stones,
And hags and rags and dirty wenches!"

in which he counted seventy *stenches*, may be termed the Rome of this side the Alps, containing more objects of interest to the architectural antiquary than any city in this position that I remember. Foremost amongst them all, however, is the cathedral, even unfinished as it is. No one who has seen it will easily forget the effect produced by it, or cease to desire that it should be worthily completed knowing as nearly all do know, that by a series of lucky accidents that some of the original drawings are preserved to us. The designs for the principal front, which it seems were formerly kept, one with the archives of the cathedral, and the other in the masons' lodge, were lost when the French occupied the city in 1794. In 1814, one of the drawings, namely that which represents the north tower, was accidentally discovered in a corn-loft at Darmstadt, by a decorative painter who was about to occupy the loft as a studio. Being drawn on parchment, it had been used for many years as the bottom of a sort of tray in which to dry beans; but with the exception of the marks left by the nails which fastened it to the wooden rim, and a fracture in the lower part of it, was little injured. It fortunately came into the possession of Dr. Möller the distinguished architect, of Darmstadt, who published a fac-simile of it in 1818. At the time of the discovery of this drawing, M. Willemin was publishing his work "*Monuments Français inédits*," and Dr. Möller was struck by the analogy which appeared between the style of a large window represented in the 12th No. of that work, and that of the details of the tower at Cologne. He mentioned the circumstance to M. Boissérée, who was then occupied on his large work on the cathedral of Cologne; inquiries were made of M. Willemin, and it was learnt that the window in question formed part of a very large drawing of a church on parchment, and then in the possession of M. Imbart, an architect at Paris, who had obtained it from M. Fourcroy. M. Fourcroy, it seems, had found it in Belgium. M. Boissérée contrived to purchase the drawing, and it was at once recognized as representing a part of the façade of Cologne cathedral.* It was afterwards sold to the King of Prussia, and His Majesty presented it to the city of Cologne. United with the drawing discovered at Darmstadt, it represents the whole of the principal front. The size of the drawings together is about 6 ft. 6 in. wide, and 18 ft. long.

The longevity, it may almost be said the *immortality*, of an idea hardly needs illustration; if it did, the design of this cathedral might in part serve the purpose. Recorded centuries ago by the mind which conceived it, the intention is but now about to be fulfilled; and what its realization at this moment may further lead to, yet remains to be seen. Another and an analogous instance is now before us. Two hundred years ago Sir Christopher Wren proposed to rebuild London with the Exchange in the centre, and the main streets radiating from this building on all sides. Circumstances were opposed to it, and the intention has lain dormant. In our day, however, one of our countrymen, called in to advise on the rebuilding of Hamburg, has re-urged this idea, and if I am rightly informed, so successfully

* It is supposed that the plan had been carried from Cologne about the middle of the 15th century, to serve as a model for the numerous churches which were then built in the Low Countries.

that the senate is about to adopt it in the new city. The emanations of the mind, like the mind itself, may be said to endure for ever—they continue to operate through the world, and to influence the future long after their origin has been lost sight of.

To return, however, to Cologne cathedral. Thanks to the power of steam, and the situation of the city on the Rhine, this structure has been viewed by most of us, and it would be impertinent to make remarks upon that with which you are as well or better acquainted with than myself. A short time ago, however, M. Daly, the editor of the "*Revue Générale de l'Architecture*," of Paris, kindly forwarded to me some information on the late repairs and decoration of the building, and an account of the enthusiastic efforts which are being made, not merely in Germany, but in other countries, to ensure the completion of the building. It is the substance of this information which seems to be sufficiently interesting to be worthy your attention, that I propose briefly to bring before you.

I may remind you that the first stone of the present building was laid on the 14th of August, 1248, and that the choir was consecrated Sept. 27, 1322, or 74 years afterwards. It was more than a hundred years after this date before the south tower was taken up to its present altitude, hardly half its proposed height; the north tower is even now not more than 20 feet, perhaps, above the ground.

When the soldiers of the French republic had possession of the city at the end of the 18th century, the cathedral was used by them as a stable, and was considerably injured. Moreover, iron cramps, which had been extensively used in the construction, caused great ravages in the stone work, and there being no funds with which to repair the evil as it became apparent, the destruction of the building seemed more than probable. After the peace, endeavours were made to restore the damage, but it was not till 1821, when the King of Prussia interfered zealously, that the matter was taken up in earnest.

In 1829 the complete restoration of the choir was commenced, (including the rebuilding of the flying buttresses, galleries, and windows,) which most desirable work is now achieved, and as it would seem most satisfactorily. A very hard and durable stone has been employed in the restoration, and the architect has studiously avoided the use of iron in the masonry, so far as was practicable, either dovetailing the stones together where additional solidity was required, or when this was deemed insufficient, employing clamps of bronze. The outlay since 1829 alone, has been more than £40,000, partly furnished by the Prussian government. The immense scaffolding which still fills the choir of the cathedral, is about to be taken down so as to expose to view the decorations that have been applied.

Beneath the whitewash with which the interior of the choir was disfigured in the last century, they discovered the painted decorations that originally adorned it, and in which the colours were applied with a sobriety and wisdom rarely met with in the works of the middle ages. All the principal parts of the construction, such as the columns and ribs, have been re-covered with a yellowish plaster, to remove the cold tint of the stones, the joints of the masonry being nevertheless left visible. The smooth surfaces of the roof are painted in imitation of the *pierre de tuf*, of which indeed the roof is constructed. Some red bands or fillets separate the light colour of the plain parts from the deeper tone of the ribs, and serve to give the latter more relief. The leaves and ornaments of the key-stones, the capitals, indeed all the sculptured portions, are gilt with a backing of bright red.

In the heads of the pointed arches above the triforium, angels are painted on a ground of sculptured ornaments, gilt. The wall of the cloister, even, is covered with paintings of the 14th century. On the interior surface they represent processions, upon a gold ground; on the exterior figures of saints, on a blue ground, powdered with stars. The mouldings of the pointed arches which enclose the figures are also very richly painted.

Fourteen colossal statues, representing our Saviour, the Virgin Mary, and the apostles, are placed against the pillars of the choir, and are said to be models of monumental sculpture and polychromatic decoration. The draperies are painted to imitate rich damask stuffs, adorned with embroideries, coloured and gilt, representing animals

and birds, executed with skill. It was much feared, in consequence of the thick coating of dirt with which time had covered these figures, that the renewal of the painting would have injured the effect of the sculpture; so far from this, however, the success is most complete.

This magnificent assemblage of architecture, sculpture, and painting, is made perfect by a series of stained glass windows, of the commencement of the 14th century, which, instead of injuring the effect of the mural paintings, by the coloured light which flows through them into the beautiful structure, harmonize the whole, and produce an effect which I can well conceive to be very striking.

The choir with its side aisles and chapels is, as already mentioned, the only part of the cathedral which is complete, the towers and nave remaining in an unfinished state—a splendid promise only, an outline of a magnificent intention, which yet remains to be filled up and made perfect. It seems possible, however, that it may not remain so much longer. Fired by the successful restoration of the ancient works, and anxious to realize the original idea in all its integrity and unity, the inhabitants of Cologne have determined on continuing the works vigorously. On the 16th of February a society was organized for that purpose, and the day was set apart for religious intercession and rejoicing. The enthusiasm displayed on this occasion is said to have been extraordinary; a procession of more than 5000 persons took part in the ceremonies of the day; Protestants and Roman Catholics, liberals and conservatives, joined on one common ground, and outvied each other in generous efforts to ensure the completion of this fine monument bequeathed by the middle ages to modern times.

This outburst of feeling on the part of the inhabitants of Cologne has been responded to, not merely throughout Germany, but in the neighbouring countries: branch societies have been formed for the purpose, literary men and artists have associated to publish magazines, the profit of which is to be devoted to the cathedral, a committee to receive subscriptions has been organized in France, and another in Rome; the King of Prussia has made himself responsible for £8000 *per annum*, and has further suggested that each of his provinces should defray the cost of one of the flying buttresses. The King of Bavaria, as in most similar instances, is not behindhand in the good work, but has formed committees in all the towns of his kingdom, and moreover has commissioned the manufactory of stained glass at Munich to produce three fine windows for the cathedral, at the cost of £3200. In Germany all classes of society, all professions, all faiths, have spontaneously united in favour of the projected work, not merely, as M. Daly suggests, under the influence of a lively interest in the welfare of the arts and for their sublime creations, or even from a sentiment of piety, but from a new-born feeling of the re-establishment of moral unity in Germany, and a desire to retrieve its ancient grandeur. Piety, art, and patriotism—love of God, love of the beautiful, love of country—unite in favour of the completion of a building in which modern Germany will give her hand to the Germany of the middle ages, across three centuries of discord. Architecture has been too often called on to embellish the triumphs of brute force; in this case it may record the willingness of a nation to be united. From the Bible we learn, continues M. Daly, that the first great monument with which architecture ornamented the world was the Tower of Babel, that is to say, of *confusion*, of *discord*. It is worthy of the architecture of our day to complete a noble edifice, high upraised, which may be at once a temple to God and a record of union.

To this I most fervently respond, and trust that the patriotic and elevated desires of the German people on this head may be fully carried out. The crane of the ancient builders has continued to surmount the grass-covered summit of the tower, mutely telling of their return, and prophesying ultimate completion.* I venture to express a hope that it may soon be seen again at work, playing its part in a much more elevated position than it is now.

GEORGE GODWIN, JUN.

* Being decayed, it was taken down in 1816, to prevent accidents, but was restored in 1819.

NOTES ON STEAM NAVIGATION.

BOILERS.—If the steam space be contracted, there will inevitably be a large consumption of fuel as well as a low degree of efficiency in the engine; for the steam will be mixed with particles of water, which will carry off much heat, and this water by entering the cylinder will endanger the safety of the engine, at the same time that it diminishes its power by resisting the motion of the piston, blocking up the ports and choking the condenser. It is only when the quantity of water which comes over with the steam is very great that these effects are obvious; but every particle of water mingled with the steam is a positive detriment, and the only effectual preventative of the evil is to make the steam space abundantly large. Mr. Watt's proportion, which is well known, is we believe better than any other.

It is a usual and judicious practice to take the steam from the highest part of the boiler or steam chest, generally by an internal pipe turning upwards and in continuation of the steam pipe. This internal pipe is sometimes made of malleable iron, in which case it rapidly oxidizes, and in the course of a year or two will often disappear altogether. Copper is the best material, and a round pipe is preferable to a square or flat one. The latter description we have known to have had its sides squeezed together by the difference of the pressure of the steam within and without it.

The oxidation of boilers is an inexplicable subject. The outsides of boilers are chiefly worn—on the bottoms by leakage, or the action of the bilge water—in the ashpits from the wetting of the ashes—and on the top from the dripping of water from the deck. The insides are subject to oxidation only above the water line—not equally over the whole surface of the iron bounding the steam space—but more in one part than another, and the difference is traceable to no specific cause with which we are acquainted. It is generally observable, however, that oxidation proceeds most rapidly upon those parts upon which the steam impinges, and also upon the parts adjacent to brass or copper. The iron in the neighbourhood of the safety and stop valves is generally the most rapidly corroded; but this effect is not invariable, nor is it known to what the want of uniformity is due. The oxide is sometimes detached in a number of consecutive black scales, like the leaves of a book, which fall off only when disturbed; in other cases no oxide adheres to the surface of the iron, and the only evidence of the existence of oxidation is the diminution of thickness in the plate, which is readily observable where two plates overlap. A very thin coat of Roman cement might be applicable to the interiors of steam chests with advantage, either in conjunction with pieces of zinc, or zincked iron, or *per se*.

Hanging bridges.—Every boiler should have a hanging bridge at the extremity of the flue where it enters the chimney, projecting downwards 18 in. or 2 ft. from the top of the flue, according to the depth of the flue and other circumstances; and the best boilers are so provided. This hanging bridge may be made either of brick or of plate iron; its effect is to retain the hot air in contact with the iron, and to permit that portion only which occupies the lower part of the flue, and is consequently the least hot, to escape to the chimney. A hanging bridge at every turn of the flue has in some instances been used with much advantage.

Furnace bars.—Where the length exceeds 7 ft. it has been found that more steam is generated and less coal burned, by shortening them. They must never be bound at both ends, nor the bearers be so constructed as to permit ashes to accumulate in the space left to allow of the expansion of the bars, else the expansion will either break the bearing bars or the brackets which support them, or the middle portions of the bars will bend up into the fire, and be quickly burned away. If there be two sets of bars in each furnace the middle bearer should be double, to allow the ashes to fall into the ash-pit through the space between the ends of the respective sets of bars. The front bearer should also be removed a little from the dead plate, and the back bearer a little from the bridge, for the same reason.

PADDLE WHEELS.—The loss of beneficial effect from backwater is not great, but there is another source of loss hitherto unnoticed, though of no trivial moment. The impulsive velocity of the several floats immersed in the water is proportional to their horizontal distances, that is, supposing that there are four floats immersed, the distance through which the first float tends to impel the vessel during its motion from the position of the first to that of the second float is equal to the horizontal distance between those floats, whilst distance through which it tends to impel the vessel during its motion from the position of the second to that of the third float being, in like manner, equal to the horizontal distance between those floats, is a very different quantity from the first. Thus there are two forces acting with different velocities at the same time, and these forces must be to a certain

extent antagonistic. If we suppose the vessel to be moving with the velocity due to the motion of the float from the first to the second position, then the excess of velocity due to the motion of the float from the second to the third position is thrown away in giving a useless velocity to the water; whilst, if we suppose the vessel moving at the latter velocity, or at a velocity approaching thereto, the floats entering the water become an actual impediment to the vessel's progress, and will carry a mass of broken water before them, in the same way as the bow of the ship, and in practice we have seen this occur. To prevent the loss of power from this source, the relative velocities of the floats should be such that the horizontal distances travelled over in equal times should be equal.

SLIDE VALVES.—It is always best for the faces on the cylinder to be formed of face plates of cast iron, from 1½ to 2 in. thick. When the engine is of sufficient magnitude to render an expansion joint in the casing expedient, the best mode of fixing the face plates is to screw them to the cylinder with countersunk bolts, both of the surfaces having been previously planed, and a little red lead interposed. In other cases it is as good a plan to fix the face plates to the valve casing, the surfaces being planed as before. The bolts which attach the casing to the cylinder will also serve to keep the face plates in contact with the casing; but they must be screwed at both ends, and have a conical enlargement in the middle to fit into the holes of the face plates, which holes must of course be made conical likewise.

No large cylinder should be faced lying on its back, for its own weight alters its form, and makes the valve face untrue; emery should not be used in grinding a valve to its surface. The most approved practice is to make the two surfaces first, as true as possible by planing; next, to try the valve on with a little reddening, and help the surfaces cautiously with a file where required; and finally, to polish with powdered Turkey stone and oil.

The effect due to a given quantity of lap or cover upon the steam and exhaustion sides of slide valves, as well as of that due to various degrees of travel in the valve, are questions looked upon as very mysterious, and they are certainly important.

If s = half the length of the stroke of the piston in inches;

s' = half the length of the stroke of the valve in inches;

t = that part of the stroke completed before the steam is cut off in inches;

t' = that part of the stroke completed before the exhausting port is shut;

s'' = that part completed before the exhausting port at the other end is opened;

c = cover on steam side;

c' = cover on eduction side;

$$\text{Then } t = s \left\{ 1 + \cos. (2 \sin.^{-1} \frac{c}{s}) \right\} \quad (1)$$

$$t' = s \left\{ 1 + \cos. (2 \sin.^{-1} \frac{c+c'}{2s'}) \right\} \quad (2)$$

$$t'' = s \left\{ 1 + \cos. (2 \sin.^{-1} \frac{c-c'}{s'}) \right\} \quad (3)$$

By these formulas the action proper to valves with any degree of cover or throw may easily be computed.

COCKS.—Every cock about an engine—gauge cocks and all—should have a bottom and a stuffing box, else they will be very troublesome as soon as they begin to leak; blow-off cocks in particular are a perpetual annoyance without this provision. The valves invented by Mr. Kingston of Woolwich as substitutes for cocks are very ingenious, and we understand operate most satisfactorily. All vessels should have these valves, or some analogous contrivance, at the place where the blow-off and injection pipes penetrate the vessel's sides, both for the purpose of preventing the escape of water into the ship in the event of the pipes being broken, and to permit the blow-off and injection cocks to be re-ground, without involving the necessity of taking the vessel into dock.

NOTES ON THE CONSTRUCTION OF BRIDGES OF CAST IRON. WITH SOME EXPERIMENTS ON THE STRENGTH OF CAST IRON GIRDERS OF LARGE DIMENSIONS.

THE basis of calculation of the strength of cast iron beams is derived from the fact of a bar one inch square and 12 inches long breaking with one ton; consequently the square of the depth, multiplied by the thickness and divided by the length in feet, gives the breaking weight in tons. In a table given in

the *Journal*, vol. iv, for 1841, p. 79, the specific gravity of cast iron is stated as 7·827, which, taking water as unity, gives 460½ lb. as the weight of one cubic foot of cast iron. It is also observed that if the gravity be different, the strength must be reduced in proportion; another authority gives 455½ lb. as the weight of a cubic foot of cast iron. Both of these weights are sufficiently near for practical purposes. The weight of metal in a structure may be found by multiplying the length in feet by the number of square inches in the section, and by 3·2 (the weight in lb. of a bar one foot long and an inch square), which will give the weight in lb.; or find the number of cubic inches, and divide the same by 3·75, which will also give the weight in lb.

In the Second Part of the Transactions of the Royal Society, 1840, is a paper "On the Strength of Cast Iron Pillars," by Eaton Hodgkinson, Esq., from which I extract the following. The ratio of strength is constant in pillars whose length is 30 times their diameter, up to 120 times, but not in shorter lengths. In the experiments, when the pillars broke, it was generally in the middle, as if the weight had been applied transversely. The theory of the comparative strength of pillars is that they vary inversely as the square of the length: e. g. a pillar half the length of another of like area, in section would have four times the strength. In the experiment the pillars broke with $\frac{1}{4}$ to $\frac{1}{2}$ the crushing weight. The crushing weight of cast iron is 49 tons, and its tensile power about an eighth of that amount. If the crushing weight of cast iron be taken at 1,000, wrought iron would be 1·745.

The rule as given by Barlow for the stiffness of cast iron beams is that it is as the cube of the depth if the weight be in the middle, and if distributed $\frac{1}{2}$ of that weight would be borne with an equal degree of deflection.

In the above extracts sufficient is developed of the theory of the strength of iron for the present purpose of illustrating these notes.

In Weale's work on bridges, we learn that iron was introduced as a main constituent of a bridge in 1775, by Thomas Fainolls Pritchard, of Shrewsbury; also that the principles that govern a bridge of carpentry are the same as for a bridge of iron, and in cast iron bearing bridges the construction must be considered as partaking more of the beam than the arch, although there are some important works in which the properties of the arch appear to have been mainly depended upon by the engineer. In the celebrated Sunderland Bridge, 236 ft. span, the versed sine being nearly that of a semi-circle, the principle of the arch is fully carried out, small portions of the arch being in frame work, like the *pend* stones or *voussoirs* of a stone bridge. In Southwark Bridge, London, of three arches, the centre 240 ft. span, and the side arches 210 ft. each, with a versed sine of 24 ft., the ribs of the arches are in long lengths, and 6½ ft. in depth. This bridge contains 3115 tons of iron: the centre arch alone contains 1665 tons. Up to 1830 there were only two cast iron bridges erected in France—the Pont des Arts, of a similar construction to Southwark Bridge, and the Pont de Austerlitz. The reason of this material not being more extensively used in that country up to 1830, was stated to be the great expense of iron, and the uncertainty of casting large pieces; although the same writer states, in favour of the use of this material, that it is adapted to bridges of large spans, and that it is as durable as stone, less expensive, more easily constructed, and, as compared with wooden bridges with abutments of stone, is one half less expense. A new construction of iron bridge has been invented by M. Polonceau, and erected at Nantes, in the Bridge of Eidre, and the Carrousel Bridge of Paris, drawings of which are given in vol. ii. of the *Journal*, p. 79: they are called Polonceau bridges after their inventor; see vol. iv. of the *Journal*, p. 92, whence the above account has been condensed. The Carrousel Bridge was completed in 1836; it has three arches, centre 187 ft. span, rise 16½ ft.; two side arches 156 ft. span, and rise 15½ ft.; width of piers 13 ft. The principle of construction is a wooden arc on the laminated principle incased with cast iron, the transverse section being elliptic and cast in 22 lengths and from its shape has been called the "tubular rib." From the preceding notes sufficient has been shown that cast iron can be used in bridges to the extent of 300 ft. span. When the circular arc is used similar to Southwark Bridge, engineers are agreed that $\frac{1}{10}$ of the chord line is a sufficient rise, and that $\frac{1}{10}$ of the span is sufficient width for the piers, the strength of the abutments being regulated merely as retaining walls. But they are not agreed whether greater depth should be given to a rib at the haunches and diminish towards the crown, or that the greatest depth should be at the crown and diminish towards the abutment.

Provided that the principle of a beam girder, brestsummer, or joist be considered as the true theory of construction, a beam parabolic on the upper edge and horizontal or level on the lower edge, and reduced at each end to one-third of its depth in the centre, will be equally strong as if its form was parallel throughout. On the London and Birmingham Railway a bridge is

constructed under the Hampstead road, where the lower edge of the beam is cambered with a versed sine of 3 ft.; the upper edge is also circular, being drawn from two centres, the extreme depth being 2 ft. in the centre, and 9 in. at each end: the span is 25 ft.; sectional area in middle 67½ superficial inches. There is another bridge on the same railway crossing Park-street, of two openings of the same span; the beams have a sectional area of 56½ in., and are horizontal at top, and cut out in the centre to the form of an arch, the spandrels being filled in solid. From the above two bridges a fair comparison may be instituted, and the inference drawn that no advantage is gained in material in adopting the arch, over the girder; and I apprehend also that the only advantage gained by the two centred or bent girders, whose elevation is a "phase" like the new moon, is in the extra depth acting in a perpendicular or ordinate line, and not on a radius line with either of the arcs. It may be also inferred that if the bridge be of large span and the arched form used, it will be necessary for calculating the breaking weight of the bridge to take the whole depth from the chord line, including the depth of the roadway bearer, and deducting therefrom the openings between the spandril fillings. Indeed no advantage is gained in confining the principal weight of iron used in the structure to the arch formed at bottom, over the equal distribution of the weight over the roadway bearer, and filling in of the spandrels. By this means the insistent weight, or the weight of the materials composing the structure, is more equally diffused over the whole erection. In farther confirmation of the above remark, that no advantage is gained in adopting the arch over the girder, I may observe that in the arched form all above the piers are cast iron, which rest upon bed frames or dead plates laid on the piers, and that the ribs are strengthened longitudinally by fillets, mouldings, flanches, &c., and that when the structure is of more bays or spaces than one, the different ribs in each arch are united by junction pieces on the piers in the direction of each rib. The ribs are also strengthened sideways with vertical diagonal frames or cross stays and distance pillars, and with horizontal diagonal braces and the roadway plates, so that the whole forms a complete square piece of framework, and may be compared to the American trellis bridge, with a circular piece cut out of it to form a headway between each pier.

But to return to the principle of construction of iron bridges, as adopted by various engineers on the railways in England. I will give a description of the different kinds of bridges which have been constructed of this material. The principle of the bow and string suspension, as employed by Mr. Leather in the bridges of Hunslet and Monk Bridge at Leeds, (the latter being 112 ft. span, the former 152 ft. span,) has been adopted on the Thames Junction Railway, and on the London and Birmingham line the same principle is applied to a bridge over the Regent's Canal at Camden Town, the roadway being on the chord line, and the ties of the bow strong bars of wrought iron: the span is 50 ft. On the same line, the road from Banbury to Lutterworth is carried over the railway on a bridge, with a span of 64 ft., in this case the road is above the bow, and the ties are distended below the chord line: the distance between the under side of the bow and tie bar is 4 ft., which is filled in with studding pieces or saddles, about the same scantling as the spandril filling of a bridge of similar span ought to be on the common construction. The same plan has been used on the Manchester and Leeds road as the bridge over the Regent's Canal; in this bridge 268 tons of wrought iron, and 155 tons of cast iron were used: a similar bridge is on the North Midland line, at Derby. This kind of bridge is used where headway under the bridge is an object. On the Birmingham and Gloucester line, at Cheltenham, a bridge is built on the above principle, where both the rib and the tie at the level of the roadway are cast iron, the lower one being suspended at a distance of 4 ft. 3 in. from the upper, with strong iron rods about the same distance apart; the tie or bottom rib has also a rise or versed sine of 18 in. On this line of railway 654 tons of cast iron, and 150 tons of wrought iron were used in bridges. On the Great Western Railway parallel girders were mostly used. In a bridge over the Paddington Canal 37 ft. span, the extreme depth of girder is 22 in., and breadth of flanch at top and bottom 9½ in., of a uniform thickness of 2½ in.; the weight of iron in the bridge is 41½ tons. A similar bridge to the last was erected over the Grand Junction Canal, in which above 73 tons of iron were used; the dimensions are as in the last example, except the span and depth of girder; the latter is 26 in. deep. The bridge over the Uxbridge road, containing 165 tons of iron, is on the principle of a framed floor of joists: the railway crosses the high road very obliquely, say 15°, at the junction of a cross road; one girder is used similar to a trimming joist, with seven others weighing about 30 tons, tenoned through it and bearing upon it. This girder weighed 9½ tons, and was 26 in. in extreme depth, with flanch at top and bottom 11 in. broad, of a uniform

thickness of $4\frac{1}{2}$ in., and $32\frac{1}{2}$ ft. long between bearings. This girder broke soon after the bridge was completed, but was replaced again without increase of weight. On the Midland Counties line the parallel girders were assisted with side rods of wrought iron, their ends being passed through cast iron lugs, on the upper edge of the girder, and the middle bent over a stud cast on the lower edge in the centre, the superstructure or roadway being generally planking, but where the girders were elliptic, the planking was placed on the lower flanch, and the back of the girder stood above the roadway. On the Great Western line the space between the girders was filled in with 9 in. arched brickwork, the girders being placed about $4\frac{1}{2}$ ft. apart. On the Pollack and Govan Railway, the Glasgow and Edinburgh, Grand Junction, and Leeds and Selby, the bridges were of the ordinary form.

The weight to be carried over a bridge or railway should be calculated for two trains passing over at the same time, and for a turnpike road the passage of troops is considered the most severe test, but in practice one of the ribs should be calculated to bear the estimated weight which it is presumed will pass over the bridge. In the Park-street bridge previously described, of 95 ft. span, an area of 56 superficial inches is given to the rib; and in No. 7 of the first table of experiments, for a span of 28 ft., with 10 tons the deflection was $\frac{1}{2}$ of an inch, the sectional area being 38 in., evidently showing the Park-street bridge abundantly strong. By a reference to the unpublished experiments on cast iron rails, you will see that the (perceptible) deflection of cast iron commences at about one-fourth of its breaking weight, so that the girder No. 7, with an area in section of 38 in. would be capable of sustaining a weight of 40 tons. The girder of the bridge that broke on the Great Western Railway at the Uxbridge road had an area of nearly 176 in., with a span of only 32 ft.

By reference to the paper in the Transactions of the Royal Society it will be seen that wrought iron will bear nearly as much again as cast iron before crushing, and by reference to Wood's experiments on rails, it will be observed that it remained elastic up to five-sixths of the weight that destroyed its elasticity, and the deflection commenced with one sixth part of that weight;

therefore, notwithstanding the greater power of its resistance to a crushing force, the greater elasticity renders it inapplicable to the purposes of bridge building on the plan of an arch.

I have been induced to extract the table from Wood's work on railways, to see whether wrought iron was applicable for bridges constructed on the common plan, having lately seen curved ribs of that material formed of railway bars acting as the support of the "lagging" of centreing, and as Mr. Pritchard (who introduced cast iron), in one of his earliest propositions on the subject, suggested cast iron ribs as a permanent centre to a back arch of masonry (Weale's Bridges, page 100).

From what has been said, I do not think wrought iron can be applied as I thought it could to large bridges. In the preceding examples of construction are the following different plans. The principle of the arch fully developed, as in Sunderland Bridge; arched ribs on the common plan, as Vauxhall and Southwark Bridges; the French tubular rib; the bow and string, as Monk Bridge, Leeds; and four descriptions of girders, viz. parallel, parabolic, parabolic curved, or one whole elevation as a phase, and the parallel assisted with tension rods; also an adaptation of the bow and string of three varieties, viz. the bridge over Regent's Canal, on the road from Banbury to Lutterworth, on the Birmingham railway, and the Cheltenham bridge on the Gloucester and Birmingham railway; being a total number of thirteen different constructions, many being used to suit localities and confined situations; but for situations where no restrictions exist, the girder is the best form up to 30 ft. span, the arched bow and string to 60 ft., the common arch to 150 feet, the framed voussoir, as Sunderland bridge, to 250 ft. and all spans larger.

As to what should be the sectional area when the common method is practised, the following particulars, collected from executed examples, may be found useful: say 25 ft. span, 30 superficial inches; 50 ft., 40; 100 ft., 110; 130 ft., 165; and the proportion of the breadth of the rib to its depth, one-fifteenth, say $2\frac{1}{2}$ inches breadth for 36 inches depth.

* With the first weight the elasticity remained, with the second weight it was destroyed.

EXPLANATION OF TABLE.

No. 1. The girders were laid together in pairs, with a block of iron between at each end, and squeezed together, and the diminution of the distance between the two girders was divided as the deflection of each. Before the pressure was applied, parallel chalk lines were struck at a small distance apart, to ascertain the position of the neutral axis, which was found to be nearly in the centre of the depth. The bearing was 9 in. from each end, and the pressure applied in the middle: the girders were kept from going back to their natural position by a strong loop of wrought iron embracing them both. The girders were elliptical on the upper edge or back, and horizontal on the lower edge; they were also strengthened on the upper edge, and had a broad flanch at bottom, and sometimes a flanch at both top and bottom. The whole of the girders, except No. 14 in the first table, were used at the Oxford and Cambridge Club. No. 14 was also used in the construction of the City of London School, Cheapside. After the above experiments, the architect in his next work, the Judge's Chambers, abandoned the fillet at top, and diminished the thickness; as for example, a girder of the same length of bearing as No. 1 in the first table had a uniform thickness of $1\frac{1}{2}$ in., depth in centre 15 in., at end 10 in., breadth of bottom flanch 4 in.: the girders at the last-named work were not proved.

No. 3. Mr. Wood calls the three divisions of the section "top, rib, and keel," the rib being the portion between the top and keel, for which two last terms I have substituted the words fillet and flanch, and for the whole three terms I have the extreme depth. No. 6 is the only rail that was parallel, which weighed 43 lb. per yard, and No. 4, which weighed only 32 lb. per yard, was elliptic or fish bellied: it retained its elasticity as long as No. 6, with an equal weight.

Mr. Wood gives one table of experiments of cast iron rails, the average weighing 55 lb., 3 ft. 9 in. between supports, being straight on the upper edge, and parabolic on the under edge; extreme depth in centre 6 in., at end 4 in.; breadth at top $2\frac{1}{2}$ in., tapering away to $1\frac{1}{2}$ in. in the middle, and swelling out at bottom into a square, each side being $\frac{7}{8}$ of an inch, and the diagonal being vertical, broke with $5\frac{1}{2}$ tons; and he observes that cast iron is very rigid, and deflection trifling before fracture, and that by mixture of metal, so as to increase its specific gravity, the same rails took $1\frac{1}{2}$ tons more weight to break them.

The following are from experiments which have not been published. A rail of cast iron, straight on top, elliptic on bottom, edge 7 in. deep in centre, $3\frac{1}{2}$ in. at each end; flanch at top $2\frac{1}{2}$ in. $\times$ $1\frac{1}{2}$ in., at bottom $1\frac{1}{2}$ in. $\times$ $1\frac{1}{2}$ in. and $\frac{1}{2}$ in. thick in the middle; with 5 tons, in the middle deflection was apparent; distance between supports 3 ft. 8 in.

At 7 tons, the deflection was $\frac{1}{16}$ of an inch.

8	"	$\frac{1}{8}$	"
9	"	$\frac{1}{4}$	"
10	"	$\frac{3}{8}$	"
11	"	$\frac{1}{2}$	"
12	"	$\frac{5}{8}$	"
12 $\frac{1}{2}$	"	$\frac{3}{4}$	" Broke instantly through its centre.

Another cast iron rail, 2 ft. 8 in. between supports; 5 in. in middle, $3\frac{1}{2}$ in. at each end, and $\frac{1}{2}$ thick; flanch at top $1\frac{1}{2}$ in. $\times$ 1 in., at bottom $1\frac{1}{2}$ in. $\times$ $\frac{7}{8}$ in.; broke with $8\frac{1}{2}$ tons; fracture in the middle, and nearly perpendicular.

St. Ann's, Newcastle-upon-Tyne.

O. T.

LIGHTNING CONDUCTORS.

A paper on lightning conductors, in connexion with the accident at Brixton Church, was lately read at a meeting of the London Electrical Society. Its author, Mr. Walker, the secretary of the society, had made a survey of the damage done to the tower of Brixton Church, and found in it so practical an illustration of Dr. Faraday's opinion on the "lateral discharge," as to induce him to investigate the subject more closely. It seems that no arrangement of metals could have been better adapted than that met with in this steeple to invite a flash of lightning to do mischief. There was a regular series of stepping-stones, as it were—first, an insulated metallic cross, then twenty feet of stone work; in passing this interval the roof of the lantern was shattered. Then come twenty or thirty feet of conductor, in the form of the clock wire, and a water pipe; and then a break of twelve feet. Here, again, was an explosion, and an immense mass of masonry was shattered

away from the base of a column intervening between the termination of the water-pipe and the commencement of the next series of conductors. Within the belfry a "lateral discharge" took place; the fluid passes from one conductor to a vicinal one for no other reason than to obtain a wider path. The author showed that electricity not only chooses a short but also a wider path; and that the "lateral spark" arises from the latter property. He then explained that it is not enough to have a continuous or an insulated lightning rod; but it is most important to have it far away from other metallic bodies; for however capacious the rod may be, and however adapted to convey, not only what passed down it, but ten thousand times more, yet, if another conductor is near, a flash will pass between the two, and ignition of neighbouring combustibles will be the result. Fortunately, in the case in question, only a small part of the whole fluid passed within the tower, consequently the lateral explosion was not severe. As it is not always possible to place lightning rods entirely out of the neighbourhood of other conductors, Mr. Walker showed that the possibility of the fluid's passing between them should then be converted into a certainty by making metallic communication between them, and thus tracing out a path along which the fluid might pass without the development of light and heat. He spoke of the peculiar property of the points of leaves, twigs, &c., in drawing off quietly charges of electricity, and stated his conviction that tall trees would always be found valuable, if not in entirely averting, at least in greatly mitigating the force of a lightning shock. The theoretical opinions given in this communication were based upon the experiments of the Royal Institution, the object of the author being to show how closely they were illustrated on the grand scale of nature, and to direct the attention of the public generally to a closer study of the properties of lightning-rods, a subject on which, perhaps, more than on any other practical point, more ignorance prevails than can be well conceived.

EXPERIMENTS AT WOOLWICH ON COAL-BOXES OF STEAM VESSELS.

On 11th May a large detachment of the Royal Artillery attended in the Marshes, to make experiments with powerful guns against the erection representing the side of a steam vessel, and the coal box. The experiments commenced at a range of 1250 yards, with 68-pounder and 56-pounder guns; Colonel Dundas' 110 cwt. gun requiring 18 lb. of powder to each charge, and Mr. Monks' 97 cwt. gun requiring 16 lb. of powder each charge, made excellent shots, but failed in passing through the coal-box, although the iron composing the interior portion of the case was rent for several inches where the balls had struck, and where they were retained, having evidently expended the greater portion of their force in passing through the coals. This result was rendered certain by the effect of one of the balls, which had passed through the portion of the erection extending beyond the coal-box, driving before it a solid piece of the wood, 12 in. square, and about 6 or 7 ft. in length, and ultimately passing through a similar thickness of wood in the rear, sinking deep into the earth composing the butt. There were three other guns, 56-pounders, respectively of 85 cwt., 84 cwt., and 67 cwt., in weight each, fired during the first six rounds, but they were then discontinued, and the practice carried on with Colonel Dundas' and Mr. Monks' guns, but they failed in destroying the coal-box to any greater extent than has been stated.

The experiments were resumed on the following day with Mr. Monks' 56-pounder gun, weighing 97 cwt. The officers in command were so satisfied with its practice, that it was ordered to discontinue firing after the 24th round. Several of the shot entered the coal-box, and caused great destruction; and although they did not pass through, they tore the joinings from the bottom to within about two feet of the top. Two more rounds were fired from the 68-pounder, one of which rent the joinings at the east end of the coal-box from the bottom to within about three inches of the top, and a great quantity of the coals fell out. The experiments with these guns, which were made at the long range of 1250 yards, having been concluded, General Millar's 10-inch gun commenced practice, having been previously placed at a range of 960 yards. The firing from this gun with shells was the best that could have been witnessed. The first shell entered the centre of the bull's eye, but did not explode, probably from the action of the loose coals through which it passed extinguishing the igniting composition before it could communicate with the contents of the shell. The second shell entered within about two feet of the bull's eye, and did not explode, probably from the same cause as in the former case. The third shell entered about nearly the same distance from the bull's eye as the second, only nearer the ground, and in six seconds exploded, throwing up into the air a flame of ignited small coals to a height of upwards of 30 ft., forming a grand and imposing spectacle, and scattering fragments of the shell, wood, and coals, to a distance of 200 yards in all directions. A fourth shell was fired, but it entered and exploded in the butt.

The experiments were again resumed on the following Friday, when it was

resolved to fire the red-hot shot 32-pounders, at a range of 800 yards. The first of these entered at the bottom of the coal-box, nearly in the same line with the bull's eye, and set fire to the wood work, which continued to burn slowly along with the ignited coals. The second red-hot shot entered about three feet from the bull's eye, and so lodged amongst the coals that it was full a quarter of an hour before the smoke of the ignited coals could make its way through the hole where the shot entered, and at the top of the box, but it afterwards rapidly gained an ascendancy, and would have consumed the whole had not the fire been put out by a party of men with the fire engine. The experiments were concluded by firing an 8-inch shell from a battery, at a distance of 950 yards, and it struck in a horizontal line with the bull's eye, tearing the eastern side of the coal-box, and exploding when it reached the back part of the box, scattering the coals, fragments of shell, and wood to a considerable distance.

It is probable the result of these experiments, which have been so far satisfactory, will give rise to others of a similar nature, as they appear to be of great importance. Were the coal boxes made of iron half an inch thick, instead of a quarter of an inch, as the one experimented with, it would afford, especially at the back, a more secure hold to the rivets of the joinings, the only parts which may be considered as having given way during the severe tests. The action of the loose coals appears to have a great effect in preventing balls passing through them when about six or seven feet in thickness, and placed in an iron box, and the discovery may prove of great importance in future fortifications, and in the defence of important stations.

IMMENSE BLOCK OF STONE, SHIPPED FOR THE NELSON MEMORIAL.

On Thursday, 9th June, we had the pleasure of witnessing the arduous undertaking of putting on ship-board this huge block of stone, weighing 30 tons, intended to form the lower part of the figure of Nelson. This beautiful piece of liver rock, when first detached from its original site in Granton quarry, was 45 tons, its under bed resting 16 ft. 3 in. below the datum line of low water at Granton Pier. It had, therefore, to be raised a perpendicular height of 40 ft. over the inclined plane of the railway leading out of the quarry to the summit level.

It was first conveyed over the floor of the quarry nearly on the level 73 ft., then up an incline 96 ft. long, having a rise of 11 ft. 9 in., a second incline 430 ft. long, having a rise of 26 ft., a third incline 112 ft. long, having a rise of 2 ft. 3 in.

This was accomplished in three days by means of logs of timber laid down, covered with a strong flat iron bar, and malleable iron rollers 3½ in. in diameter, and hauled by strong purchase crabs; nearly another day was occupied in placing it on a wagon built for the purpose, and conveying it along the railway to the place of shipping, opposite the old castle of Granton, where a dock was excavated to admit the vessel coming alongside the rock, where the shears and other powerful apparatus were fixed.

Mr. Cole, who was entrusted with the management of shipping this gigantic block, and the Government stores for the purpose, has been eminently successful in his hazardous task. It appears, that to test the apparatus and ascertain if every part was properly proportioned and efficient, on Wednesday one of the three blocks required to complete the figure, weighing 13 tons, was shipped, and every part of the bearing acting perfectly satisfactorily, it was determined to ship the large one on the following day, should the tide flow sufficiently high. At half-past one o'clock we were on the spot, when the stone had been already hoisted, and in suspension between the ponderous shears, all hands anxiously waiting for the vessel. The Albion of Goole, Captain Wright, was placed alongside, there being then scarcely sufficient water. Precisely at two o'clock the vessel being hauled into her berth, the process of lowering the shears to the required angle being accomplished with great accuracy, the purchase tackles began to move, and so gradually and steadily was all this managed, that not the least creak or surge was perceptible in any part.

In 20 minutes from the commencement of lowering away, the vessel having received the block, which put her down exactly a foot, was hauled into deep water. Although a great number of people were congregated, not the slightest noise or confusion occurred: every one seemed highly gratified, from their giving three hearty cheers, on the vessel being hauled out.

His Grace the Duke of Buccleuch has made a present of these fine blocks to the committee of management for the memorial, and we feel happy in announcing their being safely shipped without the slightest accident.

We were happy to hear Mr. Cole express his sense of the kind attention and assistance received from Mr. Hawkins, resident engineer, and Messrs. Orrell and Wightman, contractors, Granton Pier.—*Edinburgh Evening Post.*

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.

SECOND COURSE.—LECTURE VI. ON THE GAUGE OF RAILWAYS.

AFTER some preliminary observations, illustrating parts of the last lecture, and particularly in reference to what was stated respecting the Brighton railway, Mr. Vignoles proceeded to enter on the subject of the breadth or gauge of railway, which he explained to denote the distance between the iron bars which form the track or way. The definition of the gauge of the old tramways, introduced the observation that, from their form being as it were an artificial rut, they were styled by the French *ornières*, of which the literal translation was "wheel-rut." The present ordinary railway gauge was 4 ft. 8½ in., and some speculations were made as to the choice of such a particular breadth; and quotations were made from Mr. Wood's *Treatise on Railways* to show that it had been owing to an accidental circumstance—viz. that the first conclusive experiments on the principle of the present locomotive engines had been made on the Killingworth Colliery railway, which was laid to that gauge. In some of the first of the Acts of Parliament for modern railways, it had been made imperative by a special clause to adopt this particular gauge, and many companies submitted quietly to the enactment, thereby preventing all chance of improvement in what was assumed to be perfect *ab initio*; but about six years ago much discussion having taken place as to the proper gauge, this decree was altered, and there is now no limitation in the width of the gauge, which is left entirely to the discretion of the engineer. Now, the consequence is, that although it would be desirable that there should be a standard gauge fixed, yet, so divided have the public been as to what is the right one, that we have at present no less than seven different gauges used throughout the United Kingdom; some of the Scotch lines, for instance, have a gauge of 4 ft. 6 in., and others of 5 ft. 6 in. The Eastern Counties Company have adopted 5 ft. The gauge of the railways in Russia is 6 ft. On the recommendation of the Irish Railway Commissioners, the Belfast and Armagh Railway Company have made their gauge 6 ft. 2 in. On the Great Western Railway the gauge is 7 ft. Now, as much as 18 years ago, Mr. Tredgold, a celebrated and scientific engineer, made the following observations:—"The width between the rails being dependant on the height of the centre of gravity of the loaded carriage, and this again varying with the nature of the load and the velocity, it will be obvious we cannot do better than make the breadth between the rails such, that by disposal of the load, the centre of gravity may be kept within the proper limit in either species of vehicle, whether swift or slow, and it would be desirable that the same breadth and the same stress on a wheel should be adopted on all railways. We would propose 4 ft. 6 in. between the rails for heavy goods, and 6 ft. for lighter carriages to go at greater speed." Now, it is remarkable that, during all the discussions that took place with regard to the gauge, this observation was never referred to. When Mr. Brunel broke through that fixed number for the gauge, and adopted another, he gave very strong and sound reasons for so doing; whether he was right in assuming so high a number as seven is questioned by many, but the principle upon which he went was this—"I have (said he) laid out the line as nearly level as possible; the curves that I have adopted are nearly equivalent to straight lines; I keep the centre of gravity low, by placing the body of the carriage within the wheels, and anticipating greater stability and steadiness, I shall be able to go at a much higher speed, and with much more assurance of safety." The Irish Commissioners argue thus—"From the nature of the locomotive engine, its power is so great in proportion to the friction it has to overcome, that it is capable of drawing a load which (even with a greatly increased breadth as compared with common road carriages) extends to a very considerable length, and, in order to reduce this length as much as possible, it is necessary with the present breadth of way to make the wheels run within the frame which supports the carriages; the seats of the passengers are, therefore, placed above the periphery of the wheel, which, for the sake of lowering the height of the centre of gravity, is made as small as possible."

One great theoretical objection, therefore, to the narrow gauge, is the increased friction consequent upon the reduction of the diameter of the wheel, since besides what is due to the load, the friction of a wheel, at the axle, may be said to depend upon the proportion of the diameter of the wheel to the diameter of the axle; but, in attempting to carry out this principle in practice, the axle has sometimes been turned down so small as to produce much greater and more positive inconveniences, and it is very questionable if it be prudent or desirable to make the proportion between the wheel and axle greater than 15 to 1, and which proportion can be obtained with 3-foot wheels. Now, with a 4-foot wheel and a 3-inch axle, the proportion being 16 to 1, it may be well doubted if, on this account alone, the large wheels are worth their greatly increased cost. The commissioners, however, urged that the same carriage room may be preserved, by extending the breadth of bearing of the rails, so as to allow the wheels to run outside the frame, instead of running within it, in which case we can bring the body of the

riage down to the axletree. The gauge may be thus increased from 4 ft. 8½ in. to 6 ft. 2 in.—thus arguing for an increased breadth, that the centre of gravity may be lowered, and the diameter of the wheels thereby reducing the friction, and increasing the power, to overcome the "surface resistance." This is, in other words, getting more leverage; but such an advantage, however, does not apply so much to railways as to common roads, for, on the railway, there is little or no obstacle to be found in the shape of surface resistance, except what are as a few grains of dust compared with the obstacles to be found on the common road, or the deep ruts in a wood, which require very large wheels for the timber wain. "At the same time (continued the commissioners), the load itself may be reduced in height, the bottom of the carriage, or truck frame, being, in this case, limited by the axletree of the larger, instead of the periphery of the smaller wheel, and, with this reduction of height, the wear and tear will be reduced, and the ease of the motion increased. Moreover, the force to be overcome being less with the same load, we may, by retaining the power of the engine the same, carry a greater load than at present with the same velocity, or, retaining the same load, carry it at a greater velocity by increasing the diameter of the driving wheels of the engine; or, if it be not desirable to increase the velocity, the speed of the piston might be reduced, which would be a great practical advantage; or, lastly, preserving the same load and velocity, the form and weight of the engine may be made less, and, probably, the one or other of these arrangements would be adopted, according to the nature of the traffic on the railway. Thus, in passenger and mail trains, it might be desirable to increase the velocity, whereas, in the carriage of heavy goods, it would be most economical to increase the load." "But (say the commissioners) there is a point which must be attended to, and that is, that the whole of the advantages apply only to level lines." Now the Great Western was thus susceptible of having a wider gauge, since the line was made nearly level, for, as the commissioners observe, "In ascending the various gradients and inclined planes, the load has to be raised in opposition to gravity, and the power necessary to effect this is frequently equal to, or exceeds, that which is employed to overcome the friction, and will remain the same to whatever extent the friction is reduced. To avail ourselves fully of the reduced friction, those planes which cannot be worked by assistant power require to be reduced in their slopes, in the same proportion that the wheels are increased, or, otherwise, that assistant power be applied on proportionably less slopes than according to the present practice"—that is to say, that the power of the engine is employed in overcoming the friction of the load, and in raising it up the several ascents, and what is gained by increasing the breadth of the railway and making the wheels run outside the frames, is only applicable to the former, the latter remaining the same as before; "and the advantage of the alteration would be overrated if this circumstance were not taken into consideration." Thus it is that the additional advantage arising from the diminution of friction is so small, when you come to other than nearly horizontal lines, that the advantage is lost. There is yet another reason for increasing the gauge—viz. that we are enabled to construct the machine without being cramped in space for the moving parts, and affording a larger diameter for the boiler; it was this consideration, probably, which first induced practical engineers to pay attention to increasing the gauge above 4 ft. 8½ in. If we had to begin railways again, we should certainly make the gauge wider than 4 ft. 8½ in. In laying out future lines, particularly where the traffic is not great, the point of consideration will be to obtain the greatest advantage at the least expense, and to determine how much the gauge ought to be increased; and Mr. Vignoles stated, that, after having paid a deal of attention to the subject, he gave it as his opinion, that a gauge of six feet would be amply sufficient to satisfy all reasonable conditions. The Irish Railway Commissioners had observed, "that, at present, the load is seldom equal to the power of the engine, and, this being the case, but little would be gained by a greater breadth of road," with a view only of reducing the resistance, already much inferior to the power by which it is to be overcome, except by allowing an increased speed on the line generally, and on the level planes in particular. With a full and overflowing traffic, there is no doubt it would be advisable to employ the greatest possible breadth of bearing; but it is useless, or worse than useless, to incur a present expense for a benefit which it is not likely that there will ever be the means of taking advantage of, so that, unless under the circumstances just mentioned—viz. an incessant traffic, Mr. Vignoles thought that a seven-foot gauge was over the mark. Mr. Vignoles stated, that the consideration of curves was connected with that of the gauge, that it was a most important element in the consideration of railways, and would be taken up in another lecture. The rule given for raising the outer rail, on curves, required the gauge to be included as one element in the calculation, as also the height of the centre of gravity above the rails, which was also contingent on the gauge, as before explained.

INSTRUMENT FOR CALCULATING VELOCITIES ON RAILWAYS, &c.

(With an Engraving, Plate IX.)

THE instrument represented in the annexed plate, which I have named a "Velocimeter," is intended to supersede the long calculations, frequently necessary, in obtaining velocities in engine trials.

When the times of passing the quarter mile posts only are noted, such an apparatus is hardly called for, since, the distances being constant, a table may readily be made out which will give the velocities due to the different times; but it is a common practice, and perhaps a more satisfactory one, to note the times taken in traversing the several gradients, where the distances as well as the times are variable. The lengths of the inclines are generally fractional, and probably no two are the same, and none of the times of travelling over them are equal; consequently each case involves a distinct calculation, and where the trials have been extensive, several days may be occupied in making these reductions. It is, therefore, a desideratum to have some other means of obtaining the velocities, than that afforded by the ordinary methods of calculation.

The instrument devised for this purpose, is another application of that very important geometrical principle—the equality of the ratios of the sides of similar triangles. In the right angled triangle A B C (Fig. 1), let A B be taken to represent any given number of minutes and seconds, and A C the number of miles and chains passed over in that time. Then, if A B be produced until it becomes equivalent to an hour, and from its extremity D, a perpendicular be drawn intersecting A C produced in E, A E will represent the number of miles that would have been traversed in the hour had the motion been continued, that is, it will indicate the rate per hour at which the distance A C was travelled. Now, if A E be made to revolve round A, and to take any other positions, as A E' or A E'', it is clear that the relations will still be the same, and that if any distances A C', or A C'', be described in the time A B, A E' and A E'' will indicate the respective rates per hour. If, in addition to this, B C be made moveable along A D, or, what is the same thing, if A D be divided into minutes and seconds, and lines be drawn from the divisions parallel to B C, we shall be able to adjust the revolving line, to any distances and times, within the limits that may be allowed by the arrangement.

It will probably be objected, that if the line A D, representing an hour, is to be divided into minutes and seconds, its length must be so great as to make the instrument too unwieldy for common use. This difficulty is, however, very readily surmounted.

If A D (Fig. 2), be taken to represent a quarter of an hour, instead of an hour as in the last figure, it follows, that other things being the same, A E will represent one-fourth of the number of miles per hour; that is, if A E had four times the number of divisions, it would indicate the rate per hour: if, therefore, A E have two scales, one for adjustment and the other with divisions one-fourth the size for indication, the velocities may be read off as before. Or if it be desirable to make use of one-tenth of an hour, instead of one-fourth, we have only to make the indicating divisions, one-tenth of the size of the adjusting divisions, and the same result will follow.

In the application of this principle to practice, the following arrangements are made:—A D is the scale of time, embracing in this case one-tenth of an hour, or six minutes; each minute includes 15 divisions, one of which will, therefore, represent 4 seconds, and as each of these may be readily bisected by the eye, the scale may be considered as divided into periods of two seconds each. A E is the scale of distance, turning on the centre A, the adjusting scale being divided into 4 miles, and each of these subdivided into 80 chains; the same space is divided on the indicating scale into 40 miles, and each of these into eighths, ten miles on the one scale being equivalent to one on the other, in consequence of the time scale extending only to one-tenth of an hour.

To obtain results by this apparatus, the revolving scale is moved until the division answering to the number of miles and chains passed

over, is made to coincide with the division, representing the number of minutes and seconds, occupied in the transit; and this adjustment being made, the rate per hour is read off on the indicating scale, at its point of intersection with the line D B. For instance, a gradient 1 mile 25 chains long, is traversed in 2 minutes 48 seconds; what is the velocity? The divisions corresponding to these data being made to coincide, as shown at (a), the point of intersection on the indicating scale is examined, and the velocity found to be rather more than 28 miles per hour, which is the result given by calculation.

Again, a locomotive travels 1 mile 54 chains, in 4 minutes 40 seconds: required, the rate per hour. The revolving scale is moved as before, until the distance division 1 mile 54 chains at (b), is brought to (b') on the division of 4 miles 40 seconds; the edge of the scale will then occupy the line A c', and the point (c) on the scale will have arrived at the point of intersection (c'), showing the velocity to be rather more than 21½ miles per hour.

Of the three data time, distance, and velocity, any two being given, the third may be found, so that the apparatus may be employed in finding times, and distances, as well as velocities. Thus, having fixed the velocity at which the trains on a railway are to travel, and knowing the distances between the stations, the times of arrival may be ascertained, by adjusting the revolving scale to the required velocity, and noting the times corresponding to the given distances, and should the results be unsuitable, other velocities may be assumed, until the desired ends are fulfilled.

I have constructed two of these instruments, one for small, and the other for greater distances. The first (as far as I can remember, for it is not now in my possession,) is about half as large again as the accompanying drawing, and has the same arrangement, except that the indicating scale extends to 45, instead of 40 miles, and the time scale has double the number of divisions, so that differences of a second are appreciable. The other has a time scale extending to 15 minutes, each minute being subdivided into periods of 4 seconds, so that differences in time of 2 seconds are available. The scale of distance has the adjusting scale divided into 11½ miles, and each mile is subdivided into distances of 2 chains; the indicating scale extends to 45 miles, and each mile is divided into tenths. In both cases, the subdivisions of the time scale are made by lines of different colours, so as to avoid confusion.

These instruments, although made of Bristol board, and having a needle for the pivot of the revolving scale, gave results within one-eighth of a mile per hour of the truth; an approximation quite near enough for ordinary purposes. They were used for some time in engine trials, on the Birmingham and Gloucester Railway, and were found to answer very satisfactorily.

Derby, May 13, 1842.

HERBERT SPENCER.

ARCHITECTURAL DRAWINGS, ROYAL ACADEMY.

GREAT was our surprise, on looking over the catalogue, to find that the Professor of Architecture has not contributed a single drawing of any kind to the Exhibition. How are we to explain this? Are we to attribute it to the retiring modesty of true genius? Hardly so: we are, therefore, inclined to set down the Professor's absence to a different cause—certainly not to too sensitive modesty; neither does it bespeak in him any very great zeal for that department of the Academy in which he is, or ought to be, more especially interested. We own we have been disappointed, for we had made quite sure of seeing, if nothing else of his, the design for the Taylor and Randolph Institute at Oxford; more especially as he has not seemed unwilling to give publicity to it, having nearly a year ago allowed a woodcut of it to be given in one of the Oxford papers. Perhaps he has since repented of doing so, for he can hardly have heard any very favourable comments upon it; nevertheless, as the design has been seen, and as the building when erected cannot possibly be secreted from public observation, Mr. Cockerell need not have been so very shy of exhibiting any drawings of it, unless he thinks it is most prudent to steer clear of criticism as long as he can, instead of running into the very jaws of it, in Trafalgar Square. All, therefore, we can at present say, in

regard to what the Professor is doing at Oxford, is that it promises to be just such another architectural ornament to that university as the Westminster and British Assurance Office is to the Strand, which has found one, and only one, solitary admirer, viz., Mr. Britton, who, in his usual language, calls it a "fine building"! There are several other things either actually in progress, or about to be begun—that is, if there be any truth in report—which we fully expected to obtain a sight of at the Exhibition; among the rest, of the Albert Gate that is to be, leading into Hyde Park, which the newspapers have told us is to be something quite magnificent, and, therefore, we hope, will not turn out after all to be something exceedingly paltry. Neither do we see Tite's model of the portico of the Royal Exchange, as now extended, and improved from the first design, or any drawing of the inner costate, which we have heard will now be different from the published engraving of it, and which, whatever it may be as to taste, will, we trust, never be made such a palpable absurdity, in a climate like ours, as a mere open court for a place of rendezvous for business.

Sir Robert Smirke never exhibits upon paper, and had he never exhibited in stone and mortar it would have been no loss to English architecture; but Welby Pugin—we do not understand what motive he can have for never sending any drawings of the numerous catholic churches he has erected, because hardly can he shrink from a comparison of them with the majority of the designs for churches we here meet with, year after year; rather would such comparison be a triumph to the author of the "Contrasts."* It is possible that the Academy have resolved Mr. Pugin shall have no such triumph on their premises, and have, therefore, shut their doors and their catalogue against him as an audacious "Babylonian," and follower of the lady in scarlet. Others there are who seem now to have ceased exhibiting—Decimus Burton, Basevi, Salvin, Blore, &c.; nor have any provincial architects contributed a drawing of any building of note to the present exhibition. Whether it be that the profession are grown lazy, or whether they have come to the resolution of turning their backs upon the Academy, since the Academy shows very little disposition either to countenance or to back them, or to do anything for their better accommodation, we cannot say; but there certainly are some symptoms of indifference and falling off, on the part of the architects, or perhaps they have taken their cue from the Professor, who, on his part, may be loth to encroach upon the exceedingly limited space allowed for architectural drawings.

Limited as that space is, and much as it requires to be extended in one direction, we could wish to see it still more abridged in another, namely, as to height; for of the four tiers of architectural drawings hung up on the walls, only the second one from the floor, or that on the *line*, can be properly seen and examined. The other two may be seen by those who will undergo the fatigue and trouble of stooping down to the one, and standing on tiptoes to catch a sight of the other; but as for the fourth or uppermost it is impossible to see it at all. Of architectural subjects so hung, nothing whatever is discernible—nothing can be made out, except the mere general form; all detail, and even the separate features, are lost, and if this circumstance be an advantage and a favour in some instances, it becomes a great disadvantage and a piece of injustice in others. Many of the drawings put out of sight in this manner are not at all larger—several are even smaller—than those which are placed much nearer the eye. Are we, then, to understand that it matters little whether they can be discerned or not? for if so, why are they hung up at all? or why does the Academy allow its catalogue to hold out to us the promise of seeing a great many productions which, when we begin to look about for them, we find are not to be seen at all?—which tantalizing discovery, by the bye, is the most we can discover of them. In this predicament are nearly all the competition designs for the Camberwell church; the consequence is that it is impossible to compare them together, or distinguish one from another. Quite useless, therefore, is it to attempt to follow the catalogue, by taking the numbers *seriatim*; all we can do is to refer to the catalogue for the titles of such of the subjects as the eye can reach. The consequence is that, on looking over the catalogue afterwards, we invariably find that we have passed over a number of subjects which, judging from their titles, ought to be worth seeing. We reproach ourselves for our own carelessness and negligence, in omitting to take notice of so many *interesting* subjects: how could we possibly pass by such or such design, without even stopping to see what it was. And yet we should have served Barry's designs just the same, had they been placed like many others which, as far as

* How happens it that the series of "Lectures" by Mr. Pugin, so ostentatiously advertised several months ago, as being about to appear in the Art-Union, are not yet forthcoming? Did the editor find them much too "Babylonian" to be made use of; or did he begin to cackle and reckon upon his chickens before they were hatched? One or the other certainly seems to be the case.

seeing them is concerned, might just as well have been hung with their faces towards the wall, and have had their titles written in large letters on their backs.

Having mentioned Mr. Barry, we will now speak of his two interiors, Nos. 1030 and 1040, the intended Royal Gallery and St. Stephen's Hall, in the New Houses of Parliament, which are admirable as architectural pictures, masterly in execution, carefully made out in detail, without being prim or tame, and freely touched and full of effect, without that effect being at all strained or exaggerated. On the other hand, the architecture itself is pictorial and scenic; rich, but chaste, and consistent in character. Yet it is a question with us whether these drawings will satisfy the expectations of all who look at them for the effect of the proposed mode of decoration with fresco-painting,* the spaces intended to be so filled up being nothing more than a series of moderate-sized compartments, in which oil pictures or pieces of tapestry might be inserted. Except, then, those panels form part of the architectural arrangement, and are provided for painting, there is no pictorial embellishment.

Nos. 1019 and 1055, two very forcible and clever perspective drawings, showing the interior and exterior of the church now erecting at Wilton near Salisbury, by Messrs. Wyatt and Brandon, are sufficiently conspicuous, and are remarkable, not only on account of the unusual style made choice of, but for the equally unusual liberality with which the design seems to be carried out, so very different from that of the "greatest accommodation at the minimum of cost" principle adopted of late years, and which has covered the country with cheap churches, which it would be complimentary to compare to barns, they being far more unsightly—cramped with pews and galleries, for the purpose of packing a congregation together within the smallest possible compass. In proportion to the space it occupies, the Wilton church affords comparatively very few sittings; and is, besides, so uniformly decked out, and that in a manner quite contrary to established regulations, that we cannot for a moment suppose the Church Commissioners or other authorities to have been concerned with it, or that there was any competition, and a programme from a committee on this occasion. Whether the style—which is a mixture of the early Italian or Lombardic with Norman—was suggested by or suggested to the architects, we know not, but they certainly appear to have had a *carte blanche* afforded them, and to have been not at all stinted; whereas stinting and stinginess usually manifest themselves most disagreeably in nearly all our recent ecclesiastical structures, for if they make any pretension to architectural design externally, they are chillingly naked and bare within, or *vice versa*; else are they equally insipid and mean throughout. There are no indications here of the design having been pared down, and we hope that such operation will not or has not taken place in the building itself. The design, indeed, is not so entirely satisfactory that it would not have borne any additional study; but scarcely ever does it happen that the afterthoughts adopted for a building during its progress are improvements or corrections—rather quite the reverse. The omission of those ornamental expletives which, whatever share they may have had in influencing the first choice, are, on *maturer consideration*, rejected as superfluous redundances, allowed to pass in the drawings, because nothing is easier than to omit them in the building itself. The lofty square campanile at the north-west angle, detached from the church itself, except as connected with it below by a short corridor forming an internal communication between them, is not only a very marked feature—one which gives variety as well as importance to the whole exterior—but being so placed, serves to extend the front very much; and we, therefore, think its position in the plan better than that of the Stratham church campanile, which is attached to the apsis end of the building. The front itself has a good deal of rich and characteristic detail: the decorated porch below, and the large wheel window above, tell well in the design; but we apprehend that the red tiling—especially that strip of it forming a penthouse covering to the projection of the lower part of the front, within which the entrance or porch is recessed—will produce a rather crude and disagreeable effect in execution, and have a too homely, if not a positively mean and vulgar, look.

With No. 1038, "The County Assize Courts erecting at Cambridge," by the same architects, we are not so well satisfied. The style is Italian, and the composition a Doric order in pilasters, with seven intercolumns or compartments, five of which are filled in with open arches resting upon detached columns of a lesser order. The loggia

thus formed gives both character and picturesque expression; still the ensemble is neither particularly happy nor particularly original. It looks too much like a mere architectural reminiscence, without any attempt at individuality, and without much study as to detail. It strikes us, also, that the whole façade is by far too low—at least, such is the idea conveyed by the drawing, which, it must be owned, is not a particularly agreeable one, being exceedingly heavy in its shadows.

Nos. 1027 and 1050, are drawings of the Moorshedabad Palace. An elevation and plan of the Palace appeared in the Journal for May last.

No. 1037 shows us Mr. Elmes' building for the Law Courts at Liverpool, from the same point of view as the outline wood-cut drawing of it in the last volume of the *Companion to the Almanac*, but with some subsequent alterations in the design, the chief of which is that the southern portico will now be octastyle, diprostyle, instead of hexastyle, monoprostyle. It further appears, from the small plan, that the semicircular projection at the North end—a drawing of which we should like to have seen here—is considerably enlarged. But if so far there is some improvement and amplification, we perceive also that there is now some retrenchment in regard to decoration, for instead of the screen between the square pillars in the lateral divisions of the East front, having panels with subjects in bas-relief, there will be no other sculpture there than a single large wreath in each compartment, and even that may probably be eventually omitted. We regret this change in the design, for we would rather have seen something added in regard to sculpture and embellishment than the contrary. Of display with columns there is enough, a very unusual and striking degree of it, so much so that something is wanted to produce consistent richness in other respects. Therefore, if instead of adding more columns to the South portico, its pediment had been filled with sculpture, and the reliefs on the other parts abovementioned had been retained, the whole would have been materially better, a much finer piece of architecture, and of very superior quality, whereas now the quality at first promised will, we fear, be greatly abated. However, although it will not be made so much of, as the drawing and description in the "Companion" led us to expect, there will, at any rate, be one novel and happy idea in the composition, namely, the square pillars with screens between them, which, as may be seen by the present drawing, will produce a piquant effect, and serve to carry on the order uninterruptedly throughout, at the same time avoiding that wearisome monotony which it is so difficult to avoid or get rid of in Grecian architecture, without breaking up the composition, or introducing irrelevant features that more or less jar with the colonnaded portions of the design.

No. 1068 is interesting as a representation of the so-much-talked-of embellishments of the Temple Church, and certainly the vaulting of the roof is splendidly decorated in a mode almost unique in this country; yet rich and tasteful as it is in itself, we do not think it either accords with the style of the edifice, or is particularly appropriate to its character. Its gaiety and luxuriance recommend it rather for a ball or banqueting room than for a church, at least not for one which is in other respects almost bare of ornament of any kind. In the building itself the effect may, perhaps, be different—very much better; if not, the cost so incurred might have been spared, and the money more judiciously applied to the improving and embellishing the exterior of the Gothic building in the Temple, facing the garden, which, if it does not need being repaired, certainly stands in very great need of being reformed.

The two drawings by Mr. Ferrey marked Nos. 1081 and 1092, are both, we presume, views of the same building, viz. a house erecting for Chas. Porcher, Esq., at Cliff, near Dorchester, although 1092 is merely called a Design—a mistake, probably, in the catalogue, or in the earlier impressions of it—and it is to that side of the building, or its entrance front, that we give the preference, as being more piquant in character than the other, which, owing to their being so many windows, all very spacious and nearly uniform in size and design, is somewhat too monotonous, and seems to require breadth and repose. Upon the whole, however, it is a very pleasing specimen of the Tudor domestic style.

Of the three drawings sent by Mr. Donaldson, one is so remarkable that we give its title at length from the catalogue; "View of the principal part of an approved design for rebuilding Hallyburton House, Angushire, N. B., the seat of the late Lord Douglass Gordon Hallyburton, composed in the style of the Florentine palaces and villas, at the express desire of his Lordship." From this explanation it appears that the peculiar style here adopted was entirely of his Lordship's own choosing, and so far the architect is not at all responsible for what we cannot help considering a very unhappy selection, for even what are the merits of the early Florentine palazzo style, discommend it almost more than any other for a modern country mansion,

* In regard to fresco-painting, the present exhibition affords no symptoms of our artists preparing for it. On the contrary, the *Mon* in it, Maclise's "Scene from Hamlet," indicates a taste diametrically opposed to fresco, for it is completely in the wax-work style of art—perfect deception, and nothing higher.

for which purpose it is by far too stern and forbidding, and partakes, moreover, too much of town architecture. Still, although the style was forced upon him, we think there was no occasion for Mr. D. to follow it so closely. Without too widely departing from it, he might have treated it with artistical freedom—might have subdued some of its asperity, and have refined it in many other respects; instead of which, he rather seems to have exaggerated some of its least pleasing qualities. Besides what is mere matter of taste, we should apprehend that the peculiar shape of the windows, viz. two arches resting upon a central column, must not only produce a bad effect within the rooms, but be very disadvantageous in regard to internal character and mode of decoration.

No. 1118, "An Elevation of All Saints' Church, Gordon Street," is by the same architect, in a style equally unusual as that of the preceding subject. Disposed, however, as we are to welcome novelty in designs for churches which do not profess to be in the Gothic style—to welcome almost anything in preference to the customary common-place portico, generally very ordinary in itself, and thrust forth is a sort of apology for the general architectural slovenliness—we cannot say we greatly relish this specimen, and we relish still less its execution in the drawing, for in the building the shafts of the pilasters are not of stone like the other dressings, but merely of brick, owing to which and to their projecting so very slightly from the face of the rest of the wall, they are scarcely visible, distinguish themselves neither by difference of colour and surface, nor by shadow, therefore their capitals look only like so many patches of carved stone, disconnected from every thing else. What would Mr. D. himself say to columns with only their capitals in stone, and their shafts of brick-work? Most probably he would call it a great solecism in taste; and in our opinion he has committed quite as great, if not a greater one, because, at all events, the shafts of such columns would show themselves distinctly, which is not the case with those of his pilasters. The front of the church in Gordon Street exhibits far more of niggardliness in saving the paltry difference of cost between stone and brick for the pilasters than of the economy of design, for though it was deemed expedient to adopt such homely material for what are important parts in the decoration, there are three small circular slabs of coloured marble introduced in the frieze, which produce no other effect than so many small windows or pigeon-holes. There is also a good deal of carved stone work over the doors, difficult to be described, for though supplying the place of pediments to them, those large arched ornaments are altogether different from any sort of pediment. If, therefore, retrenchment was necessary at all, we think it might have been applied to these extraneous pieces of decoration, which might have been either reduced to pediments of the usual form, or omitted altogether.

1097. "Storehouses and other buildings, designed for a public company," by E. B. Lamb, is so unfavourably placed as to be in danger of being quite overlooked. It is, however, worth while stooping down, to obtain a sight of it, for it shows how much valuable effect may be produced with the simplest means by nothing more than artist-like arrangement and management; we say "nothing more," yet that nothing more seems to be very far more than architects in general can accomplish, or even seem to aim at. While so many of our public buildings, and those not the least costly ones, are, in the quality of their architecture, little better than warehouses or barracks, as, for instance, the exterior of the new portions of the British Museum, we here perceive how even storehouses might be rendered tasteful and highly picturesque architectural objects; and were the banks of the Thames lined with warehouses and storehouses similar in style to those here designed by Mr. L., the view from the bridges and from the river would afford a finer succession of architectural scenery than any other part of the metropolis. If we want a striking contrast to this, in point of taste, we have only to turn to

No. 1119, "The North and West Fronts and the Interior of the First Quadrangle of the Royal Naval School, as approved by the Council and proposed to be built at Counter Hill, Deptford." J. Shaw. This is a mere red brick house, full of windows, of most dismal physiognomy, and without any sort of pretension to architectural design; therefore it has no pretension to be thrust into an exhibition room—more especially one where room itself is so scarce that many things far more worth seeing, are thrust out of sight.

On No. 1139, with its stately Corinthian portico, first catching our eye, we had no idea that it could be other than a mere design, and were, therefore, very agreeably surprised to find, on referring to the catalogue, that it is the representation of the "Wesleyan chapel, &c." now erecting at Kingston-on-Hull, for it has certainly a far more classical look, and is withal a more varied composition, than anything similar in style in our own church architecture. Besides being an octastyle, the portico has an inner recess, with two columns in antis,

whereby it acquires a very unusual degree of effect and richness, which is further increased by the whole being raised on a stylobate terrace, out of which is cut a flight of steps forming the ascent to the portico. On this terrace are two lower buildings or wings (for the sacristy and keeper's house,) connected with the central one, by open colonnades of the Grecian Doric order. Picturesque, however, as are the arrangement and combination in this respect, we must confess we are not altogether satisfied with the design of these wings. The elevations of their sides towards the portico (with a door between two windows in each), sadly impair the general effect, and have too much the look of ordinary park lodges: the windows should be omitted here altogether, and placed of the other side. Neither is the lesser order so good as it might be, and the columns are so far apart that it looks poor and straggling, and produces a disagreeable contrast with the central portico. In fact had the lesser order been Ionic, it would have combined far better with the Corinthian one: *Memento*. Lockwood and Allom would have done well—or we may say, would have done better than they now have—had they bestowed a few second thoughts and corrections on this design.

The Wesleyans seem to be now vying with the Catholics in new structures and show of architecture, for the very next No. (1140) is "The Wesleyan Theological Institution, now erecting at Richmond, Surrey." Who Mr. A. Trimson, or Trimes, for his name is spelled both ways in the catalogue, may be, we know not, but he certainly recommends himself to us not a little by this specimen of his taste. The style is the later Gothic, and the character collegiate, with some degree of novelty also in the arrangement, there being a range of spacious and more than ordinarily ornamented windows on the lower floor, with two series of chamber windows above them.

Among those drawings which we did see, but which we have not noticed, is No. 994, "A Royal Academy for the fine arts, including a National Glyptothek and Pinakothek," by C. Tottie; nor should we mention it now, were it not to express our astonishment that such an Alexandrine-verse design, "dragging its slow length along," should have found any one to admire it. Remarkably poor and insipid in itself, it is spun out to most wearisome monotony, for it is little more than a mere string of Corinthian columns, with two rows of arched doors and windows between them. It is just such another piece of architectural insipidity as the front of the Royal Institution, Albemarle Street, or that of Chester Terrace, in the Regent's Park—monstrously prolix, exceedingly lengthy, very drawing, and intolerably dull. This is an ungracious conclusion to our remarks, but there is no help for it, for here conclude we must, unless we choose to risk the chance of being excluded from the present number.

ELECTRO-MAGNETISM AS A MOVING POWER.—The Consul-General of the Netherlands, in a communication dated the 18th April, thus announces the removal of the hitherto great obstacle to the practical application of electro-magnetism as an effective propelling power:—"A private gentleman, M. Elias, of Haarlem, has just published the description of a new machine invented by him, for the application of electro-magnetism as a substitute for steam. The object of the inventor has been chiefly to remedy the defects which, in 1839, rendered the otherwise ingenious invention of M. Jacobi, of St. Petersburg, a total failure, in as far as practical utility is concerned. Those defects originated, it seems, in the erroneous supposition that the power of the magnetic bars exclusively resides in their extremities, whence the form hitherto given to all electro-magnetic machines—viz. that of a horse-shoe—which, while it occasions an unavoidable interruption of the magnetic stream at each new inversion of the poles, at the same time leaves the power resident in the remaining part of the bars wholly unemployed. The new invention of M. Elias, on the contrary, has the very great advantage of rendering effective the full power of the magnetic stream uninterruptedly, and throughout the whole body of the apparatus. This consists of two concentric rings of soft iron, standing on the same plane, of which the external one is immovable, while that on the inside revolves round its own axis. By means of a piece of copper wire, wound about each of these rings, he has given them six magnetic poles, placed at equal distances from one another, the whole being so contrived that the one ring exerts its inducing power on the other throughout the whole circumference, and always at the same distance. A small but very perfect model of this important invention is now open to public inspection here; and the result of its operation is allowed, by those skilled in such matters, to be such as to insure the most triumphant success."

REVIEWS.

Architecture of Machinery; an Essay on propriety of form and proportion, with a view to assist and improve Design. By SAMUEL CLEGG, Jun., C.E. London: John Weale, 1842.

If the execution of this work had been at all answerable to the interest of the subject it professes to discuss, our present task would have been a more agreeable as well as a more simple one. But after a diligent perusal of Mr. Clegg's essay, we find ourselves unable to resist the conviction that its author has failed in his object, and that the consummation which this essay was intended to bring about is just as remote as ever. We feel it, therefore, in some measure incumbent upon us not merely to enter a protest against the heresies into which Mr. Clegg has fallen, but, so far as our limits will permit, to relieve the necessities his essay was meant to extinguish.

We perfectly agree with Mr. Clegg in thinking that the beauty of a piece of machinery is a consideration by no means unimportant, and it is one in our mind second only to the qualities of efficiency and convenience. We believe, with Mr. Clegg, "that the majority of those for whom machines are constructed cannot enter into the merits of their internal action, or of their comparative performance; and, therefore, not being willing to yield the right of opinion, judge from outside show, as they would of a picture or statue, where the only aim is to charm the eye, or excite pleasurable sensations in the mind." We think also that "It may, therefore, be inferred that in many instances the want of elegance in the contour of a machine is not only displeasing to the spectator, but disadvantageous to the manufacturer;" and we believe that it is disadvantageous to the manufacturer because popularly displeasing. But we cannot assent to the legitimacy of the conclusion deduced by Mr. Clegg from this proposition: we do not think it follows that, where architectural contour is unattainable without the infraction of architectural rules, it will, therefore, be the best or even the most popular course to adhere to the mechanical contour merely, or be content with those unadorned forms which science indicates as the best for withstanding the strains to which machinery is subjected. The selection of such unembellished forms we may suppose would be made by the accomplished mechanic, who would probably see in their superior scientific fitness an ample compensation for their destitution of ornament; but we can scarcely suppose such inducements to be operative with those who, without any pretensions to scientific capacity, are nevertheless disinclined to surrender their right of judgment, but judge of an engine as they would judge of a picture or statue. Upon such persons all evidences of nicety of scientific disposition must manifestly be thrown away; and they will in general esteem that to be the handsomest design which is the most exuberantly embellished. It is quite true that many of the designs to which a preference so regulated will be given must probably be ungraceful and incongruous; inconsistent perhaps with every principle of good taste, as well as with every established principle of science. But this only argues the absence of good taste among those who are pleased with such barbarisms, at the same time that it shows they are solicitous to gratify a sentiment which to them stands in the place of it. Nor can we be astonished at this depravity of taste among the multitude, when we remember how rankly it flourishes among those even with whom science is familiar, and reflect that taste is the resultant of an infinitude of influences, each slight in its individual character, and too remote and evanescent to be determinable by rules, or be susceptible of reduction to any empirical form of expression. The great majority of mankind are not only destitute of that natural sensibility upon which delicacy of taste can alone be engrafted, but are often unpossessed even of that knowledge which is necessary to enable them to distinguish glare and extravagance from true sublimity. To the less obvious or obtrusive beauties they will be insensible; they will derive pleasure from what is distasteful to those of more cultivated understandings, and will often mistake imperfections for excellence.

It appears to us then that Mr. Clegg's argument, instead of proving the propriety of engineers adapting the exterior of their machinery to the taste of their customers, rather shows that the customers ought to improve their taste, or not intermeddle. But at the same time we find that Mr. Clegg, in opposition to his own precepts, recommends a style of machinery the alleged superiority of which rests upon qualities which science alone can illustrate, and which the commonalty can neither appreciate nor comprehend. There is much inconsistency, we think, in this part of Mr. Clegg's dissertation. He first tells us, p. 2, that an attention to outside show, or, as we understand it, to em-

bellishment, is highly expedient, whilst in p. 3 he deprecates the use of any ornament whatever. "If," says he, "those parts (of machinery) are made in such a manner that they have strength in the proper place, stability without unnecessary weight, and simplicity of form without meanness, they require no other ornament, because their own proportions will constitute their greatest." We confess this looks very much like a riddle to us. The embellishment of machinery either is or is not expedient, and we should have been thankful to Mr. Clegg, had he stated a little more clearly to which doctrine his opinion inclines. From the examples of marine engine-framing which he recommends, and other circumstances, we conclude that he is hostile to the introduction of any embellishment whatever, on the principle, we presume, that that which contains everything necessary and nothing redundant is the most fit, and consequently the most beautiful. If this be Mr. Clegg's creed—and we believe that it is—we must say that we think it a very preposterous one. Fitness, though a constituent of beauty, is not the only constituent: disproportion will, it is true, give pain, and symmetry will confer pleasure; but many things, though perfectly well proportioned, and excellently adapted to their intended purposes, have very slender claims upon our admiration on account of their beauty. A barracks or a cotton mill may be as well adapted to their respective ends as St. Paul's or the Parthenon, but who would, therefore, pretend that they were equally beautiful? In like manner, an engine with a wooden beam or wooden framing, and with the malleable iron work, with the exception of the rubbing parts, just as it left the smith's anvil, may be as scientifically constructed, and in every respect as efficient as the most highly-finished engine that ever was manufactured. But who would, therefore, be prepared to maintain that it must necessarily be as handsome? We differ entirely from Mr. Clegg, in regarding fitness as synonymous with beauty; at the same time we willingly admit that beauty can never exist in perfection where fitness has not been scrupulously attended to.

In p. 16 Mr. Clegg favours us with the following definition of taste, which appears to us liable to exception:—"By the word Taste is meant that proper and well-directed exercise of the judgment by which a man acquires facility in detecting impropriety of form, and distinguishing with readiness the masterpieces of great hands from the performances of vulgar artists." Now correct taste, we contend, involves not merely the possession of a sound judgment, but of a good deal more. Any mathematician can determine the proper form of a body to resist any given strain, and a man of great knowledge and experience may be supposed capable of determining the best shape and proportion of a structure for fulfilling any required condition. But all this may be settled and the question of beauty remain untouched, and it is only indeed where the dominion of judgment ends that the empire of taste properly begins. Not that there is anything in taste inconsistent with the results which judgment has developed, or even independent of them, but that when science has exhausted her skill, another agency is available to carry us to a still higher pitch of excellence, and to heighten our enjoyment, not by any new evidences of fitness, or by any appeal to our judgment at all, but by calling into activity a multitude of hidden sympathies, and establishing a communion with the most exalted sensibilities of our nature. We do not mean to say that in looking at machinery—whatever be its character—such feelings are likely to be excited in any eminent degree; but whatever pleasure may be derived from its inspection, over and above that due to the sense of its judicious construction and arrangement, is undoubtedly due to their existence. Beauty is not to be estimated by the rule or the plummet, or computed by means of logarithms; and the author of the work before us, by reducing beauty to a mere question of fitness which may be so estimated has, in our opinion, degraded taste from her proper sphere, and proved himself incompetent for the function he has ventured to exercise.

But it is time that we should consider some of the forms of machinery with which Mr. Clegg presents us. Fig. 24 is the framing of a marine engine, as constructed by the Butterley Company; fig. 25 is the marine engine-framing of Boulton and Watt; and fig. 26 resembles the framing made by Mr. Clegg for the City of Londonderry and other vessels. There is no attempt at decoration in any of these examples, and they are all, in our estimation, far from handsome. Fig. 27 is the framing of the Wilberforce, the diagonal stay of which is curved. We agree with Mr. Clegg in thinking this curve disadvantageous, but the object was not, as he supposes, to introduce a large condenser. The stay of the framing of the Royal Tar, by the same maker, is likewise curved, although the condenser is of the usual description; and that framing has stood and lasted better than any with which we are acquainted. Fig. 28 is the framing of the Don Juan; fig. 29 the framing used by Messrs. Seaward; and fig. 30 that at one time used by Messrs. Fawcett and Co., of Liverpool: these three framings are of the Doric order. We agree with Mr. Clegg in

thinking that this order of architecture is not well adapted for the framings of steam engines; and, indeed, our opinion is that not one of the existing orders is fitted for that purpose. There is something very unmeaning in columns stuck upon the top of columns, and little columns stuck here and there over the framing, of all possible proportions and dimensions. Nevertheless, although figs. 28, 29, and 30 are indisputably architectural monstrosities, they are in our eyes less displeasing than the vapid and quakerlike arrangements shown in the preceding figures, and we believe that two-thirds of our engineers will be found to be of our way of thinking.

In much of what Mr. Clegg says about wrought iron work we perfectly concur, and we do not anticipate much opposition from engineers to the doctrine that wearing parts should be susceptible of re-adjustment, or that every portion of the moving parts should be made equally strong. We dissent, however, from Mr. Clegg when he says that the arrangement shown in fig. 53 is the most approved system of attaching the ends of rods to their cross heads (tails), and that the arrangement shown in fig. 54 is the one to be avoided. The former method consists in constructing the cross tail with a large oval hole in the centre, through which a pin passes horizontally, and to which pin the end of the connecting rod is attached by means of a strap and cutter. The advantage of this plan Mr. Clegg informs us is "that it allows some play and wear in the brasses, without giving rise to bad consequences." But the bad consequences are altogether imaginary; a few marine engines have been constructed upon this plan, but the provision has been found needless, and no engineer now thinks of employing it, especially as it is reckoned unsightly and more expensive to manufacture. The universal practice now is to attach the connecting rods to the cross tails, in the manner shown in fig. 54, which this gentleman reprehends; and we do not believe that he can adduce a single example of any ill effect having resulted from it. The angular straps shown in fig. 53 are objectionable; they are very liable to crack at the angles, and several of those of the City of London-derry have so given way. In speaking of side rod eyes Mr. Clegg says "The circular eye, fig. 57, is not calculated for equal strength, nor is the brass bush practically correct, for there is no provision for wear." We are unwilling to believe that Mr. Clegg supposes circular side rod eyes are generally or ever made without any provision for wear; for we cannot suppose any one undertaking to write upon marine steam machinery so profoundly ignorant of the subject as to be capable of entertaining any such supposition. Yet, whilst resisting this belief, we must confess ourselves unable to understand Mr. Clegg's statement on any other hypothesis.

We cannot follow this gentleman further, and have only room, in conclusion, to say that although the several ordinary orders of architecture are unsuitable for machinery—and preposterous it is to copy in iron the lineaments and proportions intended only for stone—yet there may and there must be a species of architecture adapted to this purpose, which, without interfering with the proper disposition of materials, will accommodate itself to existing shapes and conditions, and add the highest degree of grace and refinement; so that, whilst securing the homage of the superficial and uninitiated, it cannot fail to earn the approbation of the most proficient and fastidious. We anticipated from the title of his book that Mr. Clegg would have given us some examples of an architecture of this description, instead of informing us that the first principle of the architecture of machinery is that there be no architecture in it. Cast iron has its appropriate architecture as well as stone, engines as well as cathedrals, differing as much, too, from mere unembellished construction as a barn differs from an abbey. On a future occasion we may perhaps give some specimens of this architecture of machinery; at present we can only say that such an architecture exists, and it is no commendation of Mr. Clegg's essay to say that it leaves the knowledge of the subject precisely where it found it. The plates accompanying the essay are very good, though for the most part superfluous; the wood cuts are excellent, and the typography magnificent. But the thoughts are for the most part trivial and common-place, the reasonings sometimes inconsequential, the statements often inexact, and the style neither very elegant nor very perspicuous. Whatever other branches of knowledge Mr. Clegg may be skilled in, it is plain that his acquaintance with the structure of steam machinery, as well as with the resources of decorative art, is limited and superficial; and we conceive it to be unfortunate for his reputation that he has ventured upon an undertaking which renders those deficiencies so conspicuous and so inexcusable.

Memorials of Cambridge: a series of Views, &c.

Of this work, which has now reached its 29th number, and which is, therefore, approaching towards its conclusion, by no means can we report so favourably as we could wish, for instead of manifesting any improvement upon its predecessor, "The Memorials of Oxford," it shows an evident falling off in the graphic department, many of the views being uninteresting in subject, poor, spiritless, and inaccurate in drawing; and but very *so-so*ish engraved, notwithstanding that the name of J. Le Keux is affixed to them, which is all, we suspect, that there is of his in those we allude to. Mr. Bell is so decidedly inferior to Mackenzie as an architectural draughtsman, that by yoking them together in the same work its character has been rendered very unequal. Even Mackenzie himself has here somewhat disappointed us, several of the subjects by him being not fresh views, but merely repetitions of former ones by himself, and probably engraved from the same drawings as the latter. This ought not to be, more especially as many of the subjects might be shown to greater advantage by being taken from a different point of view. Hardly, too, do we complain very unreasonably, when we allege it as a fault that in some of the views the buildings themselves are shown so remotely as to be very little more than accessories in the general scene; or again, when we say that more than one piece of architecture is here very inadequately represented. In this latter predicament is the Fitzwilliam Museum, of which merely a view of the front is given, and that by no means a very good one, although it bears the name of Mackenzie as the draughtsman.* Yet as this structure is entirely a new one, more than a single drawing of it would have been very acceptable; or, at all events, there should have been one interior view, and if only one, it should have been that of the entrance hall, and sculpture gallery around it. But if little has been done with the pencil towards explaining that important public edifice, very much has been done with the pen in describing it; at any rate comparatively much, for the account of the Museum is almost the only satisfactory piece of architectural description that has yet been given in the course of the work. It is indeed so unlike any of the other "descriptions," that we almost suspect it must have been derived from some other publication; in which case it is a pity that the editors—for there are actually two employed—did not help themselves to more matter of the kind equally good. Yet of description and remarks on the respective buildings there is scarcely anything at all, although such would seem to be an almost indispensable accompaniment to a series of views—to what is a graphic publication of popular character as to size and the mode of getting up, not a library work for the antiquarian student. The "Memorials" smell too much of the laboratory of the British Museum—that admirable national establishment where old books are ground young again—a process that may in time be applied to old women also. Of most undisguised book-making the very last number exhibits a striking specimen; the account is that of Queen's College, and because Erasmus happened to reside there some time while he was in England—a fact that might have been stated in a couple of lines—we are treated with a whole history of him, for it would seem no information relative to him is to be met with in any biographical dictionary or encyclopedia. However, if the learned editors help themselves hugely to such pieces of fat, they give their readers plenty of lean, for nothing can be more meagre, jejune, and scanty, than the information to be here picked up relative to the buildings themselves. What they will say of Downing College and of the new libraries by Cockerell remains to be seen; perhaps it will turn out to be just as much and no more than what they have said of the Observatory. Mr. Le Keux has been most unfortunate in choosing his writers, for they seem to have been recommended to him by that sable gentleman who sends not only cooks, but book-makers.

Appendix C to the new edition of Tredgold on the Steam Engine and Steam Navigation. Gorgon engines, as fitted on board H.M.S. Cyclops, illustrated by ten plates and descriptive letter press. By SAMUEL CLEGG, Jun., C.E. London: John Weale, 1842.

THIS is a very valuable addition to Tredgold: the execution of the plates is perfect, and the manner in which the several objects are represented is unexceptionable. The whole of the details of the Gorgon engine are given with the sizes marked upon the several

* The design is more intelligibly shown in a woodcut view of it in the *Athenæum*, No. 512, which also contains plans of both floors; and a section of the building and other illustrations have also appeared in the *Companion to the Almanac*.

parts, so that the plates are in fact working drawings, from which the things represented might be made. This is precisely what engineers want, and have always wanted; and we are very confident that this work will be most acceptable to the profession, as well as to the public generally.

But we have higher cause of satisfaction than the excellence of the work. The drawings from which the engravings were made were supplied with the sanction of Messrs. Seaward, the constructors of the engines, who, with a liberality, and we may add a discernment, which do them infinite credit, have allowed the whole details of their engines to be published to the world. We hail this departure from the narrow and futile policy it has been too much the endeavour of engineers to pursue, in making secrets of the dimensions of their machinery, as the harbinger of a better day. The age of secrets is gone; true science and true art recognise nothing cabalistic; and merit should repudiate an auxiliary which empiricism alone does not disdain. But concealment is not only illiberal: it would be inexpedient if it were possible, and impossible if it were expedient. There is no size, proportion, or particular of any engine of any maker which may not be obtained, and which is not obtained by those sufficiently interested in the matter to take the necessary trouble. All therefore that engineers can do is to throw impediments in the way—to render the attainment of the desired information not impracticable, but only more difficult; and this difficulty will in no wise prevent those who are professionally interested in the matter from obtaining that information, however effectually it may discourage and deter those from whom no rivalry is to be apprehended, who have no prominent interest to promote, and whom it is most the interest of every engineer to illuminate. To engineers the publication of the details of the Gorgon engines will carry little information that they did not possess before, and probably among them all there will not be one who will adopt anything more of the Gorgon principle in consequence; for every engineer—even the most unskilful—is apt to consider his own modes of construction superior to all others. But with the public generally, and with steam packet companies in particular, the case is very different. They are in the dark respecting many things; they may have heard disparaging reports in reference to the Gorgon engines, which these drawings may neutralize; they may see evidences of excellence therein of which they had no previous conception; and the existence of these evidences, unbalanced by evidences of the excellencies of other engines, and which other engineers conceal, will greatly contribute to the favourable consideration of Messrs. Seawards' arrangements. The directors of steam packet companies, and indeed all unprofessional persons interested in the operations of steam power, are necessarily very impressionable; that is apt to be reckoned the best thing which is the most prominently before them, and to monopolize their attention is almost to secure their preference. It is, therefore, of the utmost moment to every engineer to bring the merits of his work forward as prominently as he can; and there is no more effectual method of doing this than by publishing the whole details of his machinery, without further note or comment than is necessary for making the drawings intelligible. One publication of this kind is better than a thousand puffing pamphlets, for such aids to notoriety are always received with aversion and distrust, and give an unfavourable complexion to the claims of those who resort to them. But an unreserved delineation of the actual parts of machinery, accompanied by an open, unbiassed, and manly statement of the reasons good or bad for the modes of construction adopted, and so explained as to be easily intelligible, can have nothing about it to repel, and it will first secure attention, next reconciliation, and finally probably adoption.

The Architectural, Engineering, and Mechanical Drawing Book, with descriptive Letter-press. London: Weale, 1842.

This work contains many plates of interesting public works, and is well adapted for the use of the younger members of the constructive professions. It consists of three divisions, viz., architecture, engineering, and mechanical drawing, giving numerous illustrations of each on a large scale. The architectural series is of 6 plates, the engineering of 14, and the mechanical drawing of 8, besides two plates of alphabets, &c. The mechanical drawings are particularly useful.

Examples of Encaustic Tiles, Part II. J. B. Nichols and Son.

The author observes that the publication of the first part of his work has elicited so many communications from parties interested in the subject, as to enable him to form the present part principally from

such communications. Instead, therefore, of being confined to specimens from Hampshire, the work now takes in other places, including at present Malvern, and the Chapter-House, Westminster; and the author states his intention of continuing the series from Malvern and Gloucester cathedral. The series from the Chapter-House, Westminster, communicated by Mr. Cottingham, is highly interesting: some of these tiles are of very complicated design.

Practical Essay on the Strength of Cast Iron and other Metals. By Thomas Tredgold. Fourth Edition, with Notes by Eaton Hodgkinson, F.R.S. London: John Weale, 1842.

TREDGOLD'S work on Cast Iron has long been admitted to be the best work upon the subject, and most deservedly has it maintained its rank for the accuracy of the tables. It is, therefore, quite unnecessary for us now to enter into the merits of the work before us. In bringing forward a new edition, Mr. Weale has done well in selecting an individual so eminent as Mr. Hodgkinson, for the purpose of editing it. He is well known for the many important experiments which he has made on iron, and which are published in the Transactions of the Royal Society, British Association, &c., all of which we hope to see in the second volume of this work. When this second volume appears, we shall not fail to notice both volumes very fully.

KIDDERMINSTER NEW CHURCH.

SIR—My attention has just been called to a letter in your journal of this month, by Mr. Wardell, strongly animadverting upon the proceedings of the Building Committee, in reference to the new church at Kidderminster, charging them with disgraceful chicanery in their mode of discharging their duties, and intimating that they never intended to act impartially between the competing architects.

Now, Sir, my plan being that originally and unanimously chosen as the best among all the other competitors, and as its eventual rejection by the Committee on the ground of its excess over the stipulated estimate in a great measure caused the unusual delay Mr. W. complains of, perhaps you will allow me very briefly to state the facts as they occurred, which, when fairly considered, place the impartiality of the Committee's intentions beyond all doubt. I may add that the fact of my plan having been originally chosen, and subsequently to my deep regret relinquished, renders me at all events an unexceptionable witness to the honour and the integrity of the Committee.

The designs were sent in on the 21st of December last: ten days afterwards my plan was pronounced the best, and I was empowered to make out working drawings, with the understanding that the final adoption of the design was to depend upon the estimate not exceeding the advertised sum. I can truly testify, that in this stage of the business, in the interviews I had with the Committee, nothing appeared more constantly before their minds than the desire to act fairly and impartially to all; and when it is remembered that their respected chairman was the Rev. T. L. Claughton, the vicar, quite a sufficient guarantee is afforded that nothing unfair would be either attempted or practised.

I was allowed a month to prepare working drawings. They were sent in Feb. 4th, and tenders from builders were advertised for in the Worcestershire papers, to be forwarded by the 1st of March. The opening of these tenders showed a considerable excess in the estimate, and the Committee, in consequence, very reluctantly felt themselves under the necessity of relinquishing my design—a proceeding of which I could not reasonably complain, however much I might regret it, since it was only in pursuance of an arrangement to which I had been a party. Three other designs having been chosen with mine, and Mr. Alexander's standing second, that gentleman was next elected; and as, upon the receipt of the tenders on the 18th of April last, the estimate came within the £3000, Mr. Alexander was appointed as the architect to the church.

These, Sir, are the simple facts of the case, and your readers will, I think, see that there is no foundation whatever for the insinuations of Mr. Wardell. I do not undertake to say that the Committee were altogether justified in keeping the drawings of the whole body of the competitors 15 weeks without any explanation till they made their final decision, but I only desire to assert, which I do from actual knowledge, that the strictest impartiality governed their proceedings, and that their uniform aim was to do justice to all, and give undue preference to none.

I am afraid this letter will hardly reach you in time for your July

number; but as its object is to vindicate a body of gentlemen as I think unjustly attacked, I trust you may be able to find space for it.

I am, Sir,

Your obedient servant,
FREDERICK FRANCIS.

251, Oxford-street.

P.S. I have said nothing about the possibility or prudence of attempting to build a *good* church to hold 1200 persons for £3000: that is another question, irrelevant to the present correspondence.

[We have also received a letter from Messrs. Starkey and Cuffley, of Manchester, on the same subject, who were competitors. They likewise confirm the impartial decision of the Committee.—EDITOR.]

ROYAL ACADEMY EXHIBITION.

SIR—Under an impression that any incident, however trifling, connected with the publicity of architectural works may be useful to some of your readers, and not uninteresting to any, I offer for insertion in your next Journal the following facts.

At the usual time for sending in pictures and drawings from which to select for the public Exhibition of this year, a perspective view of an extensive villa, which has recently been erected, and universally admired for its picturesque effect, was forwarded by the architect from a distant county, and in due time reported to be admitted. During the season the architect himself, being in London, searched in vain for this drawing in the Exhibition room; and, in reply to a consequent inquiry into the cause of its omission, was led to a back staircase, where, among many others, he recognised his *admitted drawing* quietly reposing in a corner, and having on its frame the marks of the cramps by which pictures are usually affixed to the walls, proving, of course, that it had actually been hung up. The only explanation that could be obtained of this mystery was contained in a note, stating that "in consequence of the unusually great number of works that had been sent, it was impossible for the Committee of Arrangement, with every wish to do justice to the author's talents, to find a place for his picture." It certainly is neither a miniature nor a portrait, any more than No. 992, *Pickford's Warehouses*: which I suppose is *meant* for an architectural subject!

I am, Sir,
Your obedient servant,
THE ARCHITECT.

16th June, 1842.

INSTITUTION OF CIVIL ENGINEERS.

MR. WALKER, the President of the Institution of Civil Engineers, gave his annual conversazione, on Saturday evening 4th ultimo, and as usual in addition to a most hospitable reception and good fare, supplied ample food for curiosity by a remarkably well selected collection of works of art, and models of machinery, all of which our limits will not permit us to particularize. The Admiralty, with becoming liberality, sent several of their beautiful models of men-of-war, showing the *superiority* of the mode of construction introduced by Sir William Symonds, and his talented assistant Mr. Edye; near these were appropriately placed a collection of models of improved marine engines, by Maadlays and Field, Miller, Seaward, and Fairburn. From among the multitude of other models may be selected Dockray's self-acting signal for Railways; mallets for raising ships; the Maplin Lighthouse, by Messrs. Walker and Burgess, bridges by Gravatt, Roe's arrangements for cleansing sewers; Captain Reid's water-wheel, Oldham's machine for numbering bank notes. Cheverton's mechanical carvings in ivory, and Braithwaite's pressed carvings in wood, exhibited the close alliance existing between the fine and mechanical arts. Dent's astronomical clock, made for the Emperor of Russia, and that with Professor Airy's new escapement, attracted much attention, as did also the models of Wilton Church, and the Cambridge Courts by Salter, from the designs of Wyatt and Brandon; and that of Railton's, Nelson Memorial Column, with the simple and mechanically contrived scaffolding, with which Grissell and Peto are now erecting it. A bogle horn covered with platinum by means of M. Ruolz's electro-galvanic process, showed a very successful substitution of a chemical for a mechanical process. First among the specimens of the fine arts, must be placed Thomas Landseer's beautiful engraving of *Mias Power*. Some portfolios of spirited sketches by Nixon, and by Oliver and Tatham, Bailey's busts of Fuseli; and Stoddart and his model group of charity of course were admirable, and it was scarcely fair to place so near them the busts of the President

and Mr. Sibley, which, were modelled by J. E. Jones, in which however, so much talent was displayed, that he has little cause to be distressed at any comparison, especially as we learn that he has hitherto laboured with amateur love of the art of modelling, being professionally a Civil Engineer. The principal model room was brilliantly lighted by Faraday's light, the same as that which illuminated the Throne-room at the Queen's late fête. Defries exhibited his ingenious dry gas meter in the same room, and the other rooms were lighted by Wilkins's dioptric lamps, and Cross and Blackwell's improvement upon Palmer's candle lamps.

The attendance of the Council and Members of the Institution of Civil Engineers, and also the Architects, was very numerous; there was also a very large number of visitors, many of them of high rank and distinction. The Duke of Wellington, we observed, made a complete circuit of the rooms, and examined every thing with much interest. Among the distinguished visitors we noticed particularly, the Marquis of Northampton, the Earl of Devon, Lords Bexley, Lowther, Mounteagle, Blaney, Baron Rolfe, &c.

ON THE SUPPLY OF WATER FROM THE CHALK BASIN.

THIS question has assumed such a decided character of partizanship, that we cannot allow it to remain any longer unnoticed, particularly after the recent exhibition of misstatements, garbled reports, and suppressed facts. We shall this month confine ourselves to the publication of the valuable report, being the second, by Mr. Robert Stephenson to the Directors of the proposed Company for supplying the metropolis with the pure and uncontaminated spring water from the chalk basin; and in our next number we shall enter fully into an examination of this important question, and expose the fallacious representations that have been issued to the public.

MR. STEPHENSON'S SECOND REPORT.

In my former report (see *Journal*, Vol. IV, p. 1.) I endeavoured at some length to explain the views which presented themselves to me, during an examination of the experiments made near Watford, for the purpose of ascertaining to what extent the metropolis might be supplied with water from that neighbourhood, by means of sinking shafts into the chalk formation, below the level of the valley of the Colne. In addition to a mere statement of the results, I deemed it necessary to point out some peculiarities which I conceived the chalk formation to possess, and which rendered it, in my opinion, well calculated for yielding a steady and abundant supply.

Since the publication of these views, I have lost no opportunity of carefully studying the remarks which have been made, and the objections which have been urged against the positions I then established as the basis of my opinions.

Some of these replies to my report have assumed the form of pamphlets, which separately I have not time, even if I had the inclination, to answer; but in now laying before you the results of the further inquiries, which at the close of my last report I suggested should be undertaken, to confirm or refute my opinions, I am necessarily led to notice such of the statements as appear calculated, either by the authority from which they emanate, or the plausibility with which they are adduced, to affect the views I had taken, or the conclusions which I had drawn from them.

Amongst the assailants of my opinions, are some anonymous writers; and though I feel that such a mode of attack places opponents on the vantage ground, inasmuch as they possess the privilege of making statements totally inapplicable to the matter at issue, or calculated to lead to fallacious conclusions, without subjecting themselves to any responsibility; nevertheless, in the present report, I am bound to overlook the motives by which it may be supposed some of my opponents are actuated, and while I acquiesce in such of their objections as appear well founded, to repel those which are either inapplicable, or contradicted by circumstances which have come under my own knowledge.

The pamphlet which claims my first attention is from the pen of Mr. Webster, and I give it this preference for two reasons; the first, because Mr. Webster's name is one of repute in the scientific world, and whose researches, during the early advances of geology in this country, greatly extended the knowledge of the recent formations of our Island; and the second, because it strikes at the very root of the opinions I endeavoured to expound in my former report. Both his name, therefore, and the wide and essential difference in our views, suggest the propriety of selecting his pamphlet for free and unreserved discussion; for if his statement be consistent with existing facts, the opinions which I have advanced must be erroneous, and farther consideration of your project entirely useless.

Mr. Webster denies, emphatically, that the chalk underlying the stratum of London clay is the "great water-bearing stratum," and would induce the inference, that I had mistaken the true source of supply to the numberless Artesian wells which are sunk in the metropolis and its neighbourhood. He seems to arrive at this conclusion, from my not having dwelt particularly on the "sand and plastic clay stratum," which reposes between the chalk and London clay; whereas I consider the stratum to which he alludes not the "great water-bearing stratum," but merely a subordinate member of that which may be so called.

Both the chalk and sand are extremely porous, and there can be no question that each of the "belts" of country occupied by their outcrops contributes alike its share to the supply of the great reservoir of water covered by the London clay.

In the construction of Artesian wells in or about London it is obvious, therefore, that the supply does not come immediately from the plastic clay sands; but this does not militate against my conclusion, that the reservoir formed by these sands is supplied principally by the absorption of rain, through the medium of the chalk, which occupies far more extensive areas than the plastic clay sands, and consequently possesses (even though it may not be so porous as sand) infinitely greater powers of absorption.

Mr. Webster then proceeds to state, that where wells are sunk through the London clay into the chalk, the water which the latter yields is most probably derived from the water-bearing stratum above it.

That this was the case in the Hampstead-road well (the instance quoted by Mr. Webster), I am not prepared to deny, though I much doubt the fact; but it cannot be considered conclusive against the supposition of chalk being extremely porous and absorbent, especially as innumerable examples may be referred to in every district occupied by the chalk, as incontestable evidence in its justification; moreover, many instances exist, even in London, where the supply of water to wells sunk to the plastic clay sands having proved insufficient, it has become necessary to sink them into the chalk, when an increased supply has been invariably procured; for example, in the wells at Messrs. Meux and Reid's breweries, at those at Greenwich Hospital, and Mr. Nicholson's distillery, the necessity has arisen, and been met successfully by such a process. And since no particulars can possibly be given of the sinking into the chalk in the Hampstead-road well, no general inference as to the contents and capacity of that formation should be drawn from it, more especially as other examples, upon a much larger scale, such as those above mentioned, may be quoted to prove that an augmentation in the feeders is immediately consequent upon penetrating the chalk below the sands.

I am well acquainted with the chalk district between Watford and Tring, and it having devolved upon me, in the course of my connexion with the London and Birmingham Railway, to sink a great number of wells in the chalk, my attention has been particularly called to the extraordinary quantity of water existing in the chalk immediately below the level of the natural drainage of the country—that is, of the adjoining streams, and I was at the same time struck with the conformity apparent between the surface of the subterranean reservoir of water and the natural surface of the country.

The evidence which the valley from Watford to Tring affords in reference to this point, is replete with interest, for it establishes beyond all question that the water absorbed by the chalk is held up to a very high level towards the edge of the basin; indeed, there is sufficient evidence in the district just mentioned to prove that the surface of the water absorbed by the chalk assumes an inclination corresponding almost exactly with the declivity of the valley by which the district is drained. Thus, near Watford and in the vicinity of the river Colne, all the wells require to be sunk to the level of the Colne before the supply of water is obtained; but as we proceed up the valley towards Boxmoor, Berkhamstead, and Tring, water is procured at levels corresponding strikingly with the inclination of the valley, far above the levels of the water in the wells at Watford.

The Tring cutting on the London and Birmingham Railway presents another forcible example of the constant and rapid absorption of water by the chalk. In the execution of that cutting a very large quantity of water was encountered, notwithstanding the situation was on the summit of the chalk ridge, forming the actual brim of the basin, where it could not be supplied with any water but such as fell upon the immediate neighbourhood, yet it yielded upwards of one million gallons per day, and continues to yield an extraordinary quantity up to this hour, without any sensible diminution.

This is surely incontrovertible evidence that the chalk absorbs water with the utmost facility, and as a consequence, when the levels are suitable, readily yields it up again. It may not be uninteresting to add, that previously to this work being commenced, attempts were made to sink wells to test the material from the surface of the land to the intended depth of the cutting; but so freely did the water flow from the chalk, that it was found impossible to sink several of them by ordinary means to the depth of 60 ft. Similar results have followed all experiments of this kind which I have witnessed, and those who are best acquainted with the sinking of wells throughout districts occupied by the chalk formation, concur in the opinion that it should be regarded as an enormous mass of rock saturated with water, which it yields with the utmost rapidity, by the action of a very small hydrostatic pressure.

I might here enter into a minute detail of the levels of the wells sunk in the districts occupied by chalk, which have come under my observation, were I disposed to extend this report to an unusual length; but I believe it will be more satisfactory to the committee that I should allude to the results which have been laid before me by the gentlemen who were deputed by me to examine waterworks, which are known to derive their supply entirely from such wells; with this impression, therefore, I transcribe the following extracts from the reports which have been placed before me:—

WINCHESTER.—This town is at present supplied by wells. There is a well that has lately been sunk on the hill, near the barracks, entirely through chalk, to the depth of 170 ft.; near the bottom there are fissures, out of which the water rushes with considerable violence; the water rises about

10 ft., and after pumping for seven hours successively, it is reduced 2 ft., but immediately the pumps stop working it rises again to the same height in 15 minutes.

The water is raised by the aid of an 8-horse engine working a 6-inch pump, 2 ft. stroke, and from 18 to 22 strokes per minute; at 18 strokes per minute the pump lifts 44 gallons, or 31,680 gallons per 12 hours.

At the railway station there is another well sunk in the chalk, to the depth of 80 ft.; at Christmas time there was about 4 ft. of water, and in April about 12 to 14 ft. In October, a month when the springs are generally low, the engine was kept constantly at work, day and night, for 4 or 5 weeks, and could not lower the water beyond 2 ft. from the bottom. In July, last year, after working the pump for an hour and a half, the water could not be lowered more than 18 inches. The quantity the pump lifts is the same as described above. The engineer never knew a deficiency.

Through the town of Winchester there is a very fine stream of water, which rises from the chalk hills.

I was informed, at Winchester, that at Sir William Heathcote's seat at Merton Farm there is a well in the chalk, 331 ft. deep; the water appears to pass across it like a river, with a rapid current.

Sir Thomas Baring, at his seat at Stratton Park, has sunk a well in the chalk, and is now having a steam engine erected for lifting the water to supply his estate and mansion.

ARUNDEL.—There is a well at the bottom of the town, which supplies nearly the whole of the inhabitants of that portion. It is stated to be only 20 ft. deep, sunk in the chalk; a deficiency has never been known.

The upper part of the town and the castle are supplied from a spring, which rises from the chalk in the valley, on the south-west side of the town, where there is always an abundance.

BRIGHTON.—The whole of this town is supplied with water obtained from the chalk, either by wells or from the water-works. The water-works are situated about a mile from the town, on the Lewes road, adjoining the barracks. The surface of the ground at the well is 64 ft. above high water mark. A well has been sunk to the depth of 97 ft.; at 16 ft. above the bottom there are four adits driven in from the sides of the well, to the extent of 46 ft. each, and about 6 ft. square; they are driven north, south, east, and west; the water flows into these adits from fissures in the chalk, in very considerable quantities, and appeared to flow towards the sea.

The water rises to different heights at various periods of the year; it has been as low as 58 ft. 6 in. from the surface, or 38 ft. 6 in. of water, and as high as within 8 ft. 10 in. of the surface. In the present month of April, when I viewed the works, before the engine commenced working, it stood at 31 ft. below the surface, or 66 ft. of water, and after the pumps had been working 12 hours, the water was lowered 2 ft. 9 in.; it will regain that quantity in a very short time after the pumps have ceased working.

The water is lifted by an engine of 20-horse power, working three pumps 8½ in. diameter, and three pumps 8¼ in. diameter, both 18-inch stroke, and 15 strokes per minute, lifting together 231,840 gallons per 12 hours, the time the engine works daily, Sundays excepted.

Previously to the Company being formed, there was a strong opposition in the town, and a cry that "all the wells would be dried up," but since the works have been in operation, there has not been a single complaint. The only well that was effected was one close to the works in the barrack yard: this well has been lowered a few feet, and no complaints of want of water have arisen since then.

The supply at present is to about an eighth part of the town, besides for watering the streets, and it is daily increasing. The quantity is amply sufficient for the whole town. When the springs were low in June, 1840, the six pumps were kept working day and night, for eight days, when the water could not be lowered more than 12 ft.

The pumps are fixed in the well in such a manner that either set can be raised or lowered, according to the height of the water in the well. There are two rising mains 9 in. diameter, (one to each set of pumps,) and an air-vessel, 4 ft. diameter, 6 ft. high; the delivery-pipe from the air-vessel is 12 in. diameter; near the exit it is furnished with an air-valve and a steelyard lever, loaded with about 80 lb. The water is conveyed through a 12-inch main, about a mile in length, to the reservoir, the bottom of which is 113 ft. above the top of the well, and the surface 120 ft. The water is conveyed from the reservoir by a 10-inch main to supply the eastern part of the town, and a 12-inch main, to the old Stein, then 10 in.; there are branch mains, from 5 to 10 in. diameter; the service-pipes vary from 2 to 5 in. diameter.

DOVER.—This town is entirely supplied with water from wells sunk in the chalk, and from the water-works at the lower level of the towns in Mr. Walker's yard, where there is a well sunk in the chalk below the cliff; the surface is 10 ft. above high water mark, the depth is 33 ft. 6 in., and the diameter 12 to 13 ft.; it is a tidal well; when high water, there is about 10 ft. of water, and at low water, 3 ft. The water is lifted by the aid of a 25-horse engine working two pumps, 8 and 9 in. diameter, 3 ft. 6 in., and 3 ft. stroke, and 18 to 20 strokes per minute; at the rate of 20 strokes they lift 317 gallons per minute, or 228,240 gallons in 12 hours; the water is lifted 160 ft. to the top of a tank.

This well supplies about 50,000 gallons per diem. There is another supply obtained at the gas-works, lifted by the aid of a two-horse engine.

DEAL AND WALMER.—Water-works have been lately erected about a mile to the west of Deal, which obtain their supply from a well 120 ft. deep and 6 ft. diameter, the surface being 90 ft. above low water mark; there is 16 ft.

of water standing above the bottom; there are two wells, one 110 ft. deep and the other 120 ft., which are connected together by a tunnel driven from within 4 or 5 ft. of the bottom of the deeper well to the bottom of the other; from this tunnel a very copious supply is obtained at all times; after 10 hours' successive pumping the water is lowered 10 ft., and regains it after the pumps have ceased working in three hours.

The water is raised by the aid of an 8-horse engine, working two 8-inch pumps, 22-inch stroke, and 20 strokes per minute, lifting 160 gallons per minute, or 115,200 gallons in 12 hours. There is a well within 120 yards of the above wells belonging to the mill, 90 ft. deep, which has never been effected by the pumping at the above works.

RAMSGATE.—This town is entirely supplied by wells in the chalk, and water-works; principally, however, from the latter, which obtain their supply from a well sunk in the chalk, the surface of which is 177 ft. above high water mark; the depth is 183 ft., of an oval shape, 9 and 6 ft. diameter; the lower 25 ft. is enlarged to 25 ft. diameter, from the sides of which there are two tunnels, one 42 ft. long, and the other 25 ft., which supply an abundance of water, issuing from fissures in the chalk; there is generally 26 ft. of water, which is reduced to 16 ft. after the engines have been working 12 hours. The water is raised by means of a 12-horse engine, working two 14-inch pumps in two lifts, 24-inch stroke, and 16 per minute, which lift 224 gallons per minute, or 153,720 gallons per 12 hours. There is also a smaller engine of 6-horse power, working two 9-inch pumps occasionally. The large engines are worked three days per week. The water-works supply about 700 houses, two or three breweries, malthouses, and shipping; a deficiency has never been known. There is a well belonging to a cottage within 100 yards of the above well, and 160 ft. deep, which has never been affected since the works have been erected, nor has there been a single complaint in the town.

The water is raised into an open reservoir near the engine-house, and conveyed by a 9-inch main the distance of $\frac{1}{4}$ miles to the town.

CANTERBURY.—This city is principally supplied from wells sunk in the chalk.

GRAVESEND.—This town is supplied by a well sunk in the chalk, and also by water-works near Windmill Hill, where there is a well sunk entirely in the chalk, 138 ft. deep; at the bottom there is a tunnel from which the springs issue; the water is raised by the aid of an 8-horse engine, working two 12-inch pumps, 24-inch stroke, and 10 strokes per minute, which is 195 gallons per minute, or 140,000 gallons per 12 hours.

About four years ago an action was brought against the Water-works Company by the proprietor of a well in the vicinity of the works, for a supposed injury. The proprietor alleged that his well was affected when the engine was working, and shortened his supply. The case was referred to a barrister, who examined several engineers and others, whose evidence was so contradictory that he made a personal examination on the spot: after sealing down the cover of the well, the engines were kept working, under his directions for a certain length of time; and after the time was concluded, the well was again examined. Subsequently the barrister decided in favour of the company. I have not yet been able to obtain the precise particulars of the inquiry, but the above statement shows that the barrister did not consider that the well was affected.

Nearly 40 years since a speculation was commenced, to make a tunnel under the Thames at Gravesend. A shaft was dug, and a powerful steam engine erected, a little to the westward of the gas-works, under the superintendence of Mr. Dodd, the engineer. After an expenditure of several thousand pounds, it was found impossible to get rid of the water. The stratum was chalk. The water was perfectly fresh, although the river water in this part of the Thames is brackish.

ST. ALBANS.—This town is supplied by wells sunk in the chalk, and by water-works which obtain their supply from a well sunk in the chalk to the depth of 165 ft. The water rises to the height of 19 ft., and is raised by the aid of a steam engine of 8-horse power, working a $5\frac{1}{2}$ -inch double acting pump, 24-inch stroke, and 20 strokes per minute, which lifts 82 gallons per minute, or 59,040 gallons per 12 hours. After pumping that period, the water is reduced to 9 ft. In the immediate neighbourhood of the works there are several wells, one within 20 ft., none of which were ever affected by the pumping of the above engine.

The above extracts from reports made by gentlemen who visited the various places, must, I am persuaded, go far to satisfy the most sceptical that the chalk formation is everywhere abundantly charged with water; they in fact demonstrate, that many very important towns are at this moment actually deriving their supply from that rock which Mr. Webster denies to be a water-bearing stratum; and whilst reflecting on this fact, it should not be forgotten that, in all the instances just alluded to, no resources beyond small wells and a few short drifts were required to afford supplies which should not be regarded as inconsiderable, more especially when connected with a statement that water cannot be obtained abundantly from the chalk formation.

I cannot, however, content myself with extracts from reports made by parties who may be supposed to be prejudiced in favour of the project with which they are connected. I must, therefore, insert a few passages from "Onylbare and Phillip's Geology,"—a work, whether we regard it as descriptive of the state of geological science at the period of its publication, or as a record of an extraordinary mass of practical facts intimately connected with the science, alike deserving admiration.

In speaking of the chalk formation, they say—

The lower beds of the chalk formation and every fissure, are, with few

exceptions, completely filled with water. All the rain and snow which fall upon chalk percolate downwards to the base, where the water is stopped by a sub-soil of blue clay, and that occasions it to accumulate in the chalk, until it rises to such a height as doth enable it to flow over the surface of the adjoining land."

"In this manner are formed the springs and rivulets which issue near the foot of every chalk hill."

These are the observations and conclusions acquiesced in by parties who were influenced solely by the investigation of truth. They were not swayed by any particular bias; their opinion cannot be supposed to be affected by one motive beyond those which science demands.

Having, therefore, I trust, satisfactorily proved that the chalk abounds with water, it will naturally be expected that I should meet the question of quantity; for upon this some of my anonymous assailants establish their case, not, I must confess, without a show of probability, provided we admit that what has not hitherto been done is impracticable.

I grant, at once, that the quantity of water—viz., 8,000,000 gallons per diem, which it is now proposed to raise from a shaft or shafts sunk in the chalk, has no precise precedent; but, surely, this admission is no argument against the possibility; on the contrary, I hold that the fair deduction from the above record of facts is, that *this or a much larger supply may be obtained from the chalk*, from prosecuting the sinking of shafts much deeper than has hitherto been attempted, together with the extension of horizontal driftways from the bottom of the shafts.

On mentioning the horizontal driftways, it is perhaps unnecessary to reply specifically to Mr. Webster's observations on this expedient for procuring an increased supply; for when he speaks of "groping" in the dark for water, it is obvious that he is unacquainted both with mining and with the precise nature of the construction of the chalk rock, and particularly in reference to the character of the fissures which intersect its mass in every possible direction—sometimes, it is true, more in one direction than another—easily, however, determinable by observation.

Mr. Webster playfully opens his remarks by observing that "Many are old in years, yet young in geology." This assertion I will not attempt to dispute, but state another, which I hope Mr. Webster will as readily concede—viz., "Some are old in years, yet young in mining." When Mr. Webster has spent as much of his time underground as I have done, and not till then, will he understand the exact truth of this remark. I will not permit myself, however, in this place to make any remark in disparagement of Mr. Webster, as I am convinced any observation of a personal nature never, in a question of this sort, can be substituted with propriety, for sound arguments or fair deduction.

With respect to the extent of supply, therefore, I would at once refer to every mining district in this or any other country. Can we look at Cornwall (when considering the matter in reference to the supply of water from chalk, as a rock abounding with water,) without concluding at once that increasing the depth of our shafts beyond those examples already quoted would be attended by a prodigious augmentation in the flow of water to the well. The extension of the under-ground workings of a mine, and the concomitant increase in the supply of water, are equally calculated to bring to the mind the overpowering conviction, that similar results would inevitably follow the adoption of deeper shafts and a more extended system of drifts than have hitherto been attempted in the chalk. To minds unhabituated to such consideration, these general allusions to mines may not present the same conviction; but to the experienced miner, I am persuaded the conclusions I have drawn from the facts (exhibited by the wells sunk in the chalk near Watford and elsewhere) will appear as necessary consequences.

It was my wish, in this Report, to have cited some well-authenticated particulars relative to the quantity of water raised from mines in different parts of this country, believing that they would have borne out my views in the strongest possible way; but on pursuing my inquiries upon this subject, I found that I could only arrive at general results, for it unfortunately happens that accurate records, in a shape calculated to be of value, are not kept in the various mining districts. In Cornwall, however, this remark does not apply so forcibly, for a precise record of the performances of all the pumping engines employed in draining the mines is published in "Lean's Monthly Reports."

From these Reports it is ascertained that upwards of thirty millions of gallons of water are daily raised from great depths to the surface, and from the consolidated and united mines alone, the daily quantity exceeds $5\frac{1}{2}$ millions of gallons.

There can be no doubt that, were similar records kept of the quantity of water raised to the surface in other mining districts of this country, that results equally if not more striking would be exhibited, nor should we, in the comparison, neglect to notice the fact that, unlike the chalk, the primary strata of Cornwall in which the mines are sunk possess but limited channels for the free communication of the water.

These allusions to the mining districts may be deemed, perhaps, by some, as altogether irrelevant and inapplicable to the point under consideration, since the shafts are scattered over an extensive space of country. This is certainly true when we speak of Cornwall; but the objection is to a certain degree obviated by specific allusion to the consolidated mines, and I can fortunately advert to another case, respecting the quantity of water which may be obtained from one or two shafts—an instance which, I think, must be considered unequivocal.

In the county of Durham two shafts within a few yards of one another

are now in process of being sunk for the purpose of a coal-pit. They have encountered a stratum of sand lying between the magnesian limestone and the coal formation, abounding with water to an extraordinary degree. For some months past, and up to the present moment, more than 10,000 gallons per minute, or 14,000,000 per 24 hours, have been pumped from the stratum of sand crossing these two shafts.

Here, then, surely we have an instance which proves the practicability of obtaining, within a small space, a much greater quantity of water than is sought for, or calculated upon, from the proposed shafts in the chalk.

It is probable that some may be found to urge that, even here, the cases are not absolutely parallel, the water in the one instance being drawn from sand, and in the other from chalk; but I would ask when we connect this case of quantity with those already mentioned as actually existing in the chalk, (for example, at Brighton,) can any reasonable doubt be entertained that a supply, up to the amount of 10,000 gallons per minute, or more, may be obtained from the chalk by the adoption of the means I have proposed?

Having, I believe without prejudice, most carefully weighed these and all other facts which have come before me relative to this matter, I have only to add, that I am perfectly convinced of the feasibility of the proposed plan, as far as regards quantity.

And now I beg to relinquish this part of the subject, and proceed to another, which will, doubtless, form one of the chief features in the opposition which you will encounter in laying your project before Parliament—I allude to the question whether such a quantity of water as you contemplate sending to the metropolis can be drawn from the chalk without injuriously affecting local interests?

That part of my former Report bearing upon this point was vehemently called in question by the Rev. Mr. Clutterbuck, of Watford; and as he and his relatives possess property in the neighbourhood of that place, I considered it my duty to recommend the Committee to allow Mr. Clutterbuck to suggest any experiments which he conceived were calculated to decide whether the views I entertained were correct or incorrect.

For this purpose, he suggested that the steam-engines at the experimental works near Watford should be kept at work without intermission for three days and nights; that previously to the pumping being commenced the levels of the water standing in all the adjoining wells should be accurately ascertained; that these levels should at proper intervals be again measured, for the purpose of detecting any change which might take place during the process of pumping.

I readily acquiesced in every suggestion which I thought calculated to allay those apprehensions Mr. Clutterbuck and others needlessly entertained. Accordingly, on the 3rd day of March, 1841, the necessary preliminary measurements having been made, the engines were set to work, and, at the close of the experiment, not one of the levels of the different wells was found to corroborate the objections of Mr. Clutterbuck; so far from it, there was no perceptible difference in any one of them.

It is only reasonable to expect that an experiment of this kind, undertaken expressly for Mr. Clutterbuck's satisfaction, and, as it were, under his own direction, would have enabled him to remove from his mind any impressions as to the injurious consequences which he had anticipated would result from the establishment of water-works in the immediate neighbourhood of his property; on the contrary, he adheres to his preconceived opinions, instead of deducing the most simple, obvious, and only rational conclusions from the facts developed by the experiment made at his own suggestion.

He addresses a letter to Sir John Sebright, in which he studiously avoids all detail of the experiment made at his express wish, and during which several parties were associated with him in taking the measurements, and brings forward other measurements, and observations made by himself alone, at some prior period, during the sinking of the shafts, when no regularity existed in working the pumps. He never even alludes to the wells in the town of Watford, some of which he measured with myself; he does not admit that those levels were taken with a confident anticipation on his part, that they would be instantly lowered when the pumping commenced. He makes no mention of the disappointment on finding, after three days' incessant pumping, that those levels were in no degree affected; he makes no allusion to any one of these circumstances or results that so completely negated his previous positions, and which would have carried conviction home to the mind of any unbiased inquirer after truth; but he proceeds disingenuously to select various levels of wells, taken by him at a distance of several miles from Watford, where it was quite impossible the influence of pumping could extend; yet all the variation of level in the distant wells he deliberately attributes to the pumping, without making the slightest effort to reconcile the discrepancies which would have been apparent, had he candidly recorded the results of the experiments to which I have already previously alluded. Finding, in fact, that the wells in the immediate vicinity would not tally with his notions, he calls in the aid of distant wells, where the levels, according to his own showing, were so capricious that anomalies constantly presented themselves, and in the end he adopted a theory at variance with all hydrostatic laws. To discuss it would really be a waste of time, and I think I shall be justified in treating it thus summarily, by stating that it follows from his theory, that pumping at any point in the chalk is not so likely to affect the neighbouring as the distant wells; and so distinctly is this the tendency of his theory, that he gives a diagram where the level of the water in the chalk is shown to be influenced to a far greater extent at fifteen miles than at one mile distant. Previously to the experiment being made at Mr.

Clutterbuck's request, I fully explained to him the circumstances which had led me to entertain views so diametrically opposed to his own; I explained, in the most particular manner, that those opinions were forced upon me by a long series of observations which could not be called in question; still he never refers to the facts which I communicated to him, but finishes his letter with an exposition of views totally irreconcilable with them. The series of observations I have just mentioned were brought before me during the execution of the Kilsby Tunnel, on the London and Birmingham Railway, where an extensive bed of quicksand was met with in the process of tunnelling. Before any progress could be made, it was necessary to drain the sand of water, and for this purpose several shafts were sunk and steam engines erected on the line of tunnel. As the pumping progressed, the most careful measurements were taken of the level at which the water stood in the various shafts and boreholes; and I was soon much surprised to find how slightly the depression of the water level in the one shaft influenced that of the other, notwithstanding a free communication existed between them through the medium of the sand, which was very coarse and open. It then occurred to me that the resistance that the water encountered, in its passage through the sand to the pumps, would be accurately measured by the angle or inclination which the surface of the water assumed towards the pumps, and that it would be unnecessary to draw the whole of the water off from the quicksand, but to persevere in pumping only in the precise level of the tunnel, allowing the surface of the water flowing through the sand to assume that inclination which was due to its resistance.

If this view were correct, it was evident that no extent of pumping whatever would have effected the complete drainage of the bed of sand. To test it, therefore, boreholes were put down at about 200 yards from the line of tunnel, when it was clear that, notwithstanding pumping had been going on incessantly for twelve months, and for the latter six months of this period at the rate of 1800 gallons per minute, the level of the water in the sand, at a distance not exceeding 200 yards, had been scarcely reduced.

The simple result, therefore, of all the pumping was merely to establish and maintain a channel of comparatively dry sand in the immediate line of the intended tunnel, leaving the water heaped up on each side by the resistance which the sand offered to its descent to that line on which the pumps and shafts were situated.

Observations of this description were continued for upwards of two years, and it is upon them that I rest my views respecting the drainage of the chalk, or any other porous stratum or mass, by means of pumps concentrated at a focus; indeed, when once suggested, it seems so self-evident that we may with considerable confidence predict the results of any pumping operations, under such circumstances as are found to exist in sand, chalk, or any rock or material, presenting resistance to the free motion of the liquid flowing through it. This resistance is unquestionably represented by the angle of inclination which the surface of the water assumes, and this, again, is no doubt much influenced by the size of the fragments of which the same may consist, thus giving rise to a variety of modifications in the slope of water, in different directions, from the focus of pumping.

If the above views be correct, and of which, supported as they are by indisputable facts, there can be no admission of a doubt, it follows that the result of pumping at a deep shaft, in chalk or other similar porous material, would be the drainage of a portion of the district, represented by an inverted cone, the point being at the bottom of the shaft; the upper surface, or what is generally designated the base of the cone, occupying an area depending on the inclination which the fluid assumed in passing through such porous mass. This inclination must vary with the character of the material, but in no chalk that I have ever met with can it be inconsiderable; consequently, from no extent of pumping at any one point in a formation like chalk, can the influence be apparent at any great distance.

Before I commenced the above remarks, it was my intention to have extended them into greater detail, but I found that adducing abstract calculations would tend rather to obscure than to elucidate that which is really clear and simple. I have, therefore, contented myself with such a statement as will convey, I trust distinctly, my views, and the reasons upon which they are based, and I am not without hope that the following facts are established—viz.—

1. That the chalk is the "great water-bearing stratum" underlying the London clay, and from which all the Artesian wells, directly or indirectly, draw their supplies.

2. That below the level of its natural drainage of the country it is charged with an enormous quantity of water, which may be obtained with extraordinary facility by pumping.

3. That the quantity obtainable from shafts is amply sufficient to meet the object contemplated by the Company.

These facts established, it is scarcely possible to believe that any who are interested in the supply of the metropolis with pure water will hesitate in assisting you in carrying out your project, and I cannot conclude without expressing an ardent wish that the subject may be treated by *all parties* in a liberal and impartial spirit; and I am persuaded that this new source of supply of water will soon be made available for the most important capital in the world.

ROBERT STEPHENSON.

EXPERIMENTS ON FOUR WHEELED ENGINES.

An experiment has recently been made on the London and Birmingham Railway, to show the safety of four wheeled engines when the fore-axle is broken; for this purpose the fore-axle of a four wheeled engine was cut nearly through, and in this state, was sent from the station towards Roade; the fore-axle broke in two as intended, at the point where it had been divided, but the occurrence had no apparent effect on the movement of the engine, which continued its course till it reached Roade, when it was crossed from the down to the up line, and returned in safety to Wolverton. On the following day, the engine in precisely the same state started from Wolverton, with six wagons of wheels and axles—making a gross load of thirty-two tons, exclusive of engine and tender. With this load the engine attained a speed of twenty-five miles per hour, and arrived safely at the Watford Station, distant thirty-four miles. Soon after leaving Watford, and when it was again running at a speed of twenty-five miles per hour, one of the front wheels slipped off the rails, and the engine was delayed seven minutes until it was replaced. The engine again proceeded towards London, but at about two miles beyond the Harrow Station, where the line is on transverse sleepers, the wheels once more slipped off the rails, and the engine, in that state, ran upwards of 200 yards before it was stopped. In twenty minutes it was again lifted on to the rails, and started to Camden Town, where it arrived in safety before five o'clock.

[The experiment is reported to be "highly satisfactory." For our own part we cannot see what there is to make it so "highly satisfactory;" we view the experiment in a very different light; what more serious evil can there be than an engine running off the rails as in the above case? Imagine an engine twice off the rails within the distance of ten miles! Suppose a similar accident had occurred with any other engine and train, would the tools and the men have been ready to replace the engine upon the rails within ten or twenty minutes after the accident had happened? and would the same precautions have been taken and the same look-out for the avoidance of accident? Let us hear of no more such mad-brained, hair-breadth experiments; this one is quite enough.]

THE VARIATION OF THE COMPASS.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

March 15.—The PRESIDENT in the Chair.

"Description of the Iron Skew Bridge across the Regent's Canal, on the Eastern Counties Railway." By Edward Dobson, Assoc. Inst. C.E.

This bridge is built with a direct span of 54 ft., at an angle of 79° with the centre line of the canal. The level of the rails is 14 ft. 6 in. above the water, and it is constructed to have a water-way of 44 ft., with a clear head-way of 10 ft. above the towing-path.

The dimensions of the several parts of the bridge and the mode of putting them together, with the masonry and the cost of the construction, are described in detail, and illustrated by an elaborate working drawing.

As an appendix to this paper a description is given of a bridge over the same canal, on the line of the London and Birmingham Railway, on account of the similarity of its construction. The span of this latter bridge is 50 ft., but being made for two double lines of rails, it was thought expedient to have three main ribs instead of two, as in the former. The details of construction of this bridge are also given, with a drawing of one of the main ribs and its tie-bar.

"Remarks on the Ravages of the Worm (*Teredo Navalis*) in Timber." By Robert Davison, M. Inst. C.E.

This communication describes the ravages committed by the "Teredo

Navalis" upon the fir piles of the foundations of the old bridge at Teignmouth, five arches of which, after having been built only 12 years, fell suddenly; the construction of a new bridge thus became necessary, and it is now in progress under the direction of Messrs. Walker and Burges. The worm is described as entering the wood through a hole not larger than a pin, and perforating the timber in all directions, but chiefly in the direction of the fibre, at the same time increasing the size of the holes even sometimes to an inch diameter; a few of the worms had been found of the extraordinary length of 3 ft. They confine their operations between low-water mark and the bottom of the river, showing that they cannot exist out of water.

A specimen of part of a log picked up off Jersey was as much perforated, but in a different manner, the worms having penetrated the wood indiscriminately all over the surface; in some cases leaving in the holes a coat resembling the tail of a lobster about 3 in. in length, which showed that the ravages had been committed by the "Lymnoria Terebrans."

The paper was also accompanied by a specimen of wood sheathing charged with nails, from the bottom of a vessel believed to be about 100 years old, together with some of the worms ("Teredo Navalis"), for the purpose of showing the peculiar shape of the head—resembling a pair of forceps, with which they cut away the wood.

"Description of the Roof of Messrs. Simpson and Co's Factory." By John Boustead, Grad. Inst. C.E.

The truss of this roof is double, consisting of two frames of Memel timber. The principals are fitted into cast iron shoes resting on the walls, with projections let into the wall plates; they taper towards the ridge, and there abut against a cast iron ring-piece, through which a wrought iron bolt 1½ in. diameter passes, and answers the purpose of a king-post in supporting the collar-beam. To the under side of this beam is attached a heel and eye-plate, to either end of which are linked bolts passing between the principals, and secured by nuts at the backs of the shoes, thus forming efficient ties to resist the thrust of the principal rafters.

The slate-boards are supported by five purlins 4 ft. apart, and abut against a ridge-piece resting on the kings.

The span of the roof is 34 ft. 3 in. The pitch is about 3 to 1, and the principals are placed 9 ft. apart.

The scantlings of the principal timbers are:—Principals 9½ by 2½ in. tapering to 6½ by 2½ in.; collar-beam 7 by 3½ in.; purlins 6 by 4 in.; wall-plates 6 by 4 in.; slate-boards 1 in. thick; ridge-piece 10 by 2 in.

The principals were sawn out by a template, so as to insure the given taper and the accuracy of the angles of the ends; they were then laid in a horizontal position placed at the required angle, and the collar-beam inserted ½ in. deep into each principal, and secured by bolts ½ in. diameter; the mode of raising the roof is then described.

Some of the advantages of roofs of this construction are stated to be, economy in materials and workmanship, with lightness and simplicity, and that all sagging of the timbers may be rectified by screwing up the nuts of the kings and shoes.

The truss is recommended for buildings where lofty apartments or coved ceilings are required, and also for its presenting so few points for the suspension of heavy weights that may subject the timbers to strains for which no provision has been made.

From the examinations that have been made, this roof seems to answer satisfactorily; it has been erected three years and a half, and has sustained heavy falls of snow, but the ridge and rafters have preserved their lines perfectly, and the walls show no signs of having been subjected to undue pressure. The design of the roof is simple, its appearance light, and it may be considered an interesting specimen of the art of simple carpentry assisted by iron-work.

A drawing of the truss accompanied the paper.

ACADEMY OF SCIENCES.

April 4.—M. Siguer read a paper *On the means of preventing the explosion of boilers in steam vessels*, or of confining the effects of such explosions, when they do occur, within very circumscribed limits. He recommends, as a general principle, that the boilers should be composed of many distinct parts (tubes), so that in the event of the rupture of any one portion, there may be no injury beyond the engine-room, and that the metal of which they are composed should be thin, in order that it may not be deprived of its tenacity in the process of manufacture; and he insists upon strict attention being paid to their shape, which should, he says, be spherical, cylindrical, or conical, as being best calculated to offer an equal resistance to the explosive power.

M. Arago communicated the result of some experiments made with the view of solving the long-disputed question as to whether the transmission of light is more or less rapid, according to the density of the medium through which it passes, and reported his experiments before the Academy in proof that the transmission is not equally rapid.

M. Dupasquier read a paper *On the use of iron as a test in Marsh's apparatus for the detection of arsenic*. M. Dupasquier stated unequivocally, that by the use of a preparation of iron, such as had been resorted to at times by chemists intrusted with the task of testing the presence of arsenic, stains apparently arsenical, but which are not so, may be produced.

April 11.—A paper was read by M. Domeiko, *On the silver mines in Chili*, and the mode of working them. The mines extend from the north to the south, parallel with the coast, to a distance of 150 leagues from the environs of St. Yago to the other side of Copaiipo. The silver mines of Acqueros, which are the special subject of the paper communicated to the Academy, were discovered in 1825 by a mulatto, whilst collecting wood on the mountain. He found by chance several small blocks of native silver, and, having mentioned his discovery to his acquaintances, they proceeded to the spot, and collected immediately silver to the value of 10,000 dollars. Soon afterwards the vein itself was discovered, and its richness was found to equal all that had been anticipated. From that period up to 1840, the date of the last returns, this vein has yielded about 30,000 marcs of silver annually.

A paper was read *On the Daguerreotype improvements of M. Bisson*. M. Bisson, by a galvanic process, covers the plate with a slight coating of silver, much more even and perfect than the surface of the ordinary silvered plate, and the object was, consequently, represented with greater fidelity and boldness. Another improvement of M. Bisson's is, in giving, by the action of the galvanic pile, a slight gold tint to the drawing, which takes away its unpleasant looking-glass appearance, and causes the objects to stand forth almost as clearly and vigorously as in drawings produced by hand.

April 18.—A paper was read by M. Regnault, *On the dilating powers of gases, and on the relative powers of air and mercurial thermometers*.

A specimen of a reddish sediment, deposited by a shower of rain at Amphissa, in Greece, on the night of the 24th ult., and forwarded by M. Bourros, with a paper on the subject, was examined by the Academy. The last mail from Smyrna brought an account of a similar fall of rain at about the same time. One of the journals of that place, alluding to this phenomenon, states, that the sediment resembled the sand of the desert, and supposes it to have been taken up by a whirlwind, and, combining in the clouds with water, to have been held in suspension until it had travelled to a distance of nearly 1,000 miles to Smyrna. The wind, adds the *Smyrna Journal*, was blowing fresh from the southward at the time, bringing heavy clouds, accompanied by a peculiarly hazy atmosphere, observable only in long continued siroccos.

May 3.—A paper was read from M. Reville, of Havre, *On the use of cotton sails for ships*, as more economical than those made from flax, and being at the same time equally serviceable. Certificates from various persons who have made use of cotton sails, and specimens of their old and new were laid before the Academy.

From Messrs. Hempel and Hamann, *On a new Compass, of their invention, for measuring ellipses*. The report of Col. Puissant and M. Sturm on this invention, which was read to the Academy, states it to be superior to any instrument for the same purpose hitherto known; consequently, the Academy decided on expressing publicly its approbation of the invention.

From M. Jobard, of Brussels, on some experiments which he proposes to make, with a view of ascertaining the best means of preventing the explosion of steam boilers. The principal experiment proposed by M. Jobard is, such a construction of the boiler as will permit, when the mixture of explosive gases has been formed, the introduction of a stream of atmospheric air, so as to render them inexplosive.

From M. de Castelnau, *On some geological revolutions in the central parts of North America*. The period to which M. de Castelnau directs the attention of the Academy is that corresponding with the geological revolution to which the bordering portions of Canada and the United States owe their present configuration, viz. that which formed the great Lake of Canada, extending from east to west, with the exception of Lake Michigan, the direction of which is from the north to the south, with a slight deviation towards the west. At the south of the southern point of this lake, there extend toward the Ohio on the one side, and the Mississippi on the other, vast prairies, entirely formed of deep alluvial soil covering an old calcareous bed. Every thing indicates, says M. de Castelnau, that this region was formerly the basin of a lake of much greater extent than those which now exist in this part of the world, and, on approaching the Mississippi, the proofs of this phenomenon become more evident. He considers it certain, that at a remote period there was some obstruction to the course of the Mississippi, which produced a stagnation of its waters, and raised them to an elevation of 40 metres; for wherever the rocks present an abrupt front towards the river, they offer a series of parallel lines, inclining slightly towards the north. The geological formation of the land in the vicinity of Lake Huron, presents the character of a vast Silurian formation. According to M. de Castelnau, Lake Superior formerly discharged itself into Lake Michigan, which had its termination in an immense basin, to which he gives the name of Lake Silurian, and which probably discharged the excess of its contents into the Mexican Sea; but a revolution of nature checked the passage of the waters to the extremity of Lake Michigan, and produced at Lake Silurian the rising ground known as the Illinois, which must have been of greater extent than it is now, and it is not impossible, that with its progressive depression, the waters will at some distant period resume their former course.

May 9.—At a special meeting M. Cordier communicated various details relating to the horrible accident on the Versailles railroad, extracted from an official report addressed to the Minister of the Interior by Messrs. Combes and De Senarmont, the engineers of Mines, charged with the inspection of rail-roads. In addition to the facts already known, it states that the foremost locomotive was a small one, with four wheels, and the other one of large dimensions with six wheels, made by Sharp and Roberts. The boilers of both are at present without the slightest injury. According to the testimony of the Commissary of Police of Meudon, one of the carriages was altogether consumed in ten minutes. The report contains the following summary as to the cause of the calamity. The accident originated in a fatal concurrence of circumstances, which were all gross faults, easy to have been foreseen, and still more easily to have been avoided. The first cause of the accident was the employment of a locomotive with four wheels. It is essential that every carriage intended for service on a railroad should rest on six wheels at least, in order that if one of the axles should break, the carriage should rest on supporters, and continue its course. The second fault consisted in the employment of two locomotives for a single train. The consequences of this arrangement are self-evident. A third circumstance was, the precaution taken to lock the door of the wagons; so that in such a case as that which occurred, all escape was prevented, and the travellers were condemned to suffer all the consequences of the first accident. Another cause which had much influence on the catastrophe, was the neglect to isolate the train from the locomotive, so as to prevent the shock occasioned by the sudden check to the speed with which they were proceeding. It is worthy of remark, that if all those causes had not existed together, and if only a single precaution had been taken, the accident would not have happened. If the first engine had been furnished with six wheels when its axle broke, it would not have lost its equilibrium. If a second locomotive had not been employed, the only consequence of the accident would have been a shock; and, even admitting that the two first causes of the accident existed, had the doors of the wagons not been locked, a number of the passengers might have escaped the flames; and the interposition of the elastic system would have saved the train even if no other precaution had been observed. The Academy listened to the account in mournful silence. Several members afterwards made remarks on the inconvenience of using locomotives with four wheels; M. Elie de Beaumont particularly protested against immense trains being drawn by several locomotives, the danger increasing in proportion to the number of machines employed. The custom of locking up the passengers was also much spoken against. Towards the close of the sitting, a rumour having spread in the Academy that Admiral Dumont d'Urville was amongst the number of the dead, or at least that he had not been found after the accident, it being certain that he had entered one of the foremost wagons, M. Arago proposed that two members should be appointed to make inquiries respecting him; and if they found him among the wounded, to testify to him all the interest that the Academy took in his fate.

A report by M. Seguin, was read, of a series of experiments performed by order of the Academy on the cuirass made of hemp, the invention of M. Papadapoulo. The report states, that the balls of cavalry pistols, fired at a distance of from three to five paces, only penetrate to a depth of about the third of an inch; consequently, the report is favourable to the inventor; but a discussion having arisen on some points not alluded to in the report, the decision of the Academy, as to the value and importance of the invention, stands over until the points under discussion shall have been treated upon by the reporter.

MISCELLANEA

The Monster Steam Ship.—This vessel, which is nearly ready to be launched, is built by three or four spirited individuals on their own speculation in the small town of Derry, Ireland, where a few months previously it was never supposed that a vessel of her magnitude would ever be built; her dimensions are 222 ft. in length between perpendiculars, 37 feet beam, and 26 feet deep in the hold, burthen 1750 tons, B.M., she is to be fully rigged as a 50 gun frigate, the length of main mast to be 90 ft. and 33 inches diameter, main yard 79 ft. and 22½ ft. diam. in the slings, foremast 83 ft. and mizen mast 76 feet, she will be able to spread 6,400 yards of canvas. There are three decks, the upper one to be left entirely clear for action, and to be pierced for 44 guns, the windlass and capstan gear will be placed on the next decks. She is to be propelled by Smith's Archimedean Screw, which will be 12 ft. diam. and 14 ft. pitch, but the length will be only 7 ft.; it is to make 88 revolutions per minute, the gearing consists of a cog wheel 20 ft. diam., working into a smaller wheel of 5 ft. diam., upon whose axis is the shaft of the screws. The engine power consists of two cylinders 66 in. diam., 4 ft. 6 in. stroke, and to make 22 strokes per minute, nominal power 306 horses; there are to be four air pumps 19 in. diam. and 4 ft. 6 in. stroke, and 3 cylindrical boilers. The engines are to be placed close abaft the vessel, leaving the midships clear for passengers.

A very beautiful stained glass window has recently been put up over the altar of West Hackney church, the centre part of which is a copy of the celebrated altar-piece at Magdalen College, Oxford—Christ bearing the cross, very finely coloured, from the original picture; and on either side stand out in bold relief the figures of St. Paul and St. Peter, after Raphael. They stand in

miches, which have a very striking effect, the metal work being so contrived as to have the appearance of one sheet of glass. The whole of the subjects have been got up in a masterly style, are beautifully drawn and coloured, and reflect much credit upon Mr. Holder, the artist, of Gray's-inn Road. We understand that the subjects were selected by the excellent taste and judgment of the rector, the Rev. Mr. Birch, and at whose sole expense the whole has been completed.

Marylebone Paving Association.—This Association for the improvement of Street Paving is one highly worthy of the consideration of the professions, and of the support of those interested in the parish of Marylebone. We shall enter upon the subject of wood paving next month.

Conservative Club.—We understand that the designs for the new building are entrusted to Mr. Sydney Smirke, and Mr. Basevi, who are appointed conjointly architects for carrying out the design, which it is reported will be upon a magnificent scale.

St. Austen Cornwall.—An Act of Parliament has been obtained for the purpose of effecting considerable improvement in this town, and the Commissioners have decided upon erecting a new town hall and market. Designs for which were submitted in competition, and that by Messrs. Eales and Cope of Bloomsbury Square, London, has been selected by them for execution. The façade is in the Italian style to be executed in granite. The cost £5000.

Standing Orders.—In the House of Commons on Thursday, 23d ult., Mr. Wilson Patten brought forward the motion of which he had given notice, namely, "That so much of the Standing Orders of this House as obliges promoters of Railway Bills to give their notices, and to deposit their plans and sections in the months of February and March, instead of the months of October and November, be repealed." The motion was carried without the slightest opposition.

The Royal Tar, Peninsular steamer, having undergone a thorough repair in London by Messrs. Miller, Ravenhill, and Co., who have put in new boilers, thereby effecting a wonderful reduction in the consumption of fuel, went down to Southampton, and made an experimental trip, under the inspection of Mr. Lamb, the government engineer. She is now on duty with the Peninsular mails.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 28TH MAY TO 23RD JUNE, 1842.

Six Months allowed for Enrolment, unless otherwise expressed.

WILLIAM YOUNG, of Queen-street, lamp-maker, for "improvements in lamps and candlesticks." Sealed May 28.

PHILIP JACOB KAYSER, of Gracechurch-street, manufacturer, for "improvements in the construction of lamps." May 31.

HENRY PHILLIPS, of Exeter, chemist, for "improvements in purifying gas for the purposes of light." May 31.

RECHARD WATSON, JUN., of Cloth-fair, gas fitter, for "improvements in draining land embankments, and cutting of railways and other engineering works." May 31.

HENRY WILKINSON, of Pall Mall, gun-maker, for "improvements in unloading shipping, especially those vessels called colliers." May 31.

LOUIS NICHOLAS DE MECHERHEIM, of Vienna, but now of London, engineer, for "improvements in the manufacture of iron." May 31.

HENRY BEAUMONT LEESON, of Greenwich, doctor of medicine, for "improvements in the art of depositing and manufacturing metals and metal articles by electro-galvanic agency, and in the apparatus connected therewith." June 1.

WILLIAM HENRY KEMPTON, of South-street, Pentonville, gentleman, for "improvements in the manufacture of candles." June 1.

JAMES REED, of Bishop's Stortford, statuary and mason, for "improvements in tiles, slating, and the construction of water-tight joints, and in the covering and casing of buildings and other erections."—June 2.

HENRY JUBBER, of Oxford, confectioner, for "improvements in kitchen ranges, and apparatus for cooking."—June 2.

BENJAMIN AINSWORTH, of Birmingham, gentleman, for "improvements in the manufacture of glass, for the purpose of producing glass which may be used for the purposes to which plate glass and window glass are usually applied."—June 4.

EDMUND TUCK, of the Haymarket, St. James's, Westminster, silversmith, for "improvements in the covering or plating with silver various metals and metallic alloys."—June 4.

WILLIAM IRVING, of Regent-street, Lambeth, engineer, for "an improved corn drill, or machine for sowing all kind of seed or grain."—June 7.

JOHN WOODCOCK, of Manchester, millwright, for "improvements in the construction of steam-engines."—June 7.

JAMES NASMYTH, of Patricroft, near Manchester, engineer, for "certain improvements in machinery or apparatus for forging, stamping, and cutting iron and other substances."—June 9.

JOSEPH CHATWIN, of Birmingham, lamp-maker, for "improvements in the construction of cocks."—June 9.

JOHN GEORGE HUGHES, of No. 158, Strand, general agent, for "a new application of telegraphic signals, and the mode of applying the same."—June 9.

JAMES ANTHONY EMBLE, of the Borough and County of Newcastle-upon-Tyne, civil engineer, for "certain improvements in pumps."—June 9.

STEPHEN BENDRAFT, of Barnstaple, gentleman, for "improvements in the construction of saddle-trees."—June 9.

ARTHUR HOWE HOLDSWORTH, of Breck-hill, Devon, gentleman, for "improvements in constructing certain parts of ships and vessels in order to arrest the progress of fire, and for regulating temperature."—June 11.

RICHARD GARRETT, of Leiston Works, Suffolk, agricultural instrument maker, for "improvements in the construction of horse-hoes, scarifiers, drag-rakes, and drills, for cultivating land." June 13.

THOMAS BANKS, of Manchester, engineer, for "improvements in the construction of wheels and tyres of wheels, to be employed upon railways."—June 13.

MORIS POOLE, of Lincoln's-inn, gentleman, for "improvements in obtaining the colouring matter from wool, and woollens dyed with indigo." (Being a communication.)—June 13.

WILLIAM COTTON, of Leytonstone, Essex, Esquire, for "an improved weighing machine."—June 13.

DANIEL WILLIAMS, of Oxford, slater, for "improvements in covering ridges and hips on the roofs of buildings."—June 13.

ISAAC MOSS, of Macclesfield, Cheshire, silk trimming manufacturer, for "improvements in the manufacture of covered buttons, ornaments and fastenings for wearing apparel." June 13.

WILLIAM MORRETT WILLIAMS, of Bedford-place, Commercial-road, and of 163, Fenchurch-street, lock manufacturer, for "improvements in the construction of locks and keys, which he proposes to call 'Williams' lock and key improved.'"—June 13.

HENRY HOUGH WATSON, of Bolton-le-Moors, consulting chemist, for "improvements in bleaching, changing the colour of, and otherwise preparing, purifying and refining tallow, and certain other organic substances, mixtures, compounds, and manufactures."—June 21.

JOSEPH BUNNETT, of Deptford, Kent, engineer, for "improvements in pavements, for streets, roads and other surfaces, and in machinery for producing and repairing the same."—June 21.

JOHN DICKSON, of Brook-street, Holborn, engineer, for "improvements in rotary engines and boilers, in stopping railway carriages, and in machinery for propelling vessels, part of which improvements are applicable to propelling air and gases."—June 21.

FREDERICK GYE, JUN., of South Lambeth, gent., for "improvements in binding pamphlets, papers and other documents."—June 21.

THOMAS GAUNT, of 10, Dalby-terrace, City Road, gent., for "improvements in the means of applying any such power as is or may be used for propelling vessels or carriages to produce locomotion thereof."—June 21.

HENRY BEWLEY, of Dublin, licentiate apothecary and chemist, for "an improved chalybeate water."—June 23.

TO CORRESPONDENTS.

"Connecting Rod"—The question of Long and Short Connecting Rods has already occupied a considerable portion of the Journal.

Seyton's communication will appear next month.

B. G.—If the engine of 10 tons weight be of just sufficient power to draw a train of 50 tons weight at 20 miles an hour on an even plane, it will require 66-100th additional power to convey the said train at the same rate up an inclined plane of 16 ft. in the mile, and double the power up an inclined plane of 24 ft. in the mile.

"Beale's Rotary Engine."—A. H. P.'s remarks on this engine came too late for insertion this month; we think they had better be deferred until we have reported some further experiments that are about to be made, which will appear in the next month's Journal. In our account of the performance of the "Anti John Scott Russell" we omitted to notice that the distance from London Bridge to Greenwich, performed at the first trip in 39½ minutes was against a strong tide.

T. F.—We are compelled to defer this communication until next month.

Books Received—Memoirs of the Literary and Philosophical Society of Manchester, Vol. VI.; Mr. Grantham's work on Iron Ship Building; and "On the Use of Mechanical Power;" which will be noticed next month.

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 30th instant.

Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume

ERRATA.

Strawberry Hill.—In our last number, the engraving is stated to be the "Ground Plan," instead of which it ought to have been the "Principal Floor"; and instead of letter e in the recess, it should have been r; and the opening shown as a door should have been a window; the letter e ought to have been placed opposite to the window of the room C.

Page 205, col. 2, line 3, of Reviews, for Practical Geology, read Practical Geodesy.

THE THREADNEEDLE STREET STRUCTURE.

PUBLIC attention has been excited in a very unusual degree by this building. And no wonder: for, in the first place, the character of the design is in many respects not a little striking in itself; in the next, people were quite taken by surprise when, the scaffolding or screen before it being removed, they beheld what, for this country, may be termed an almost unprecedented display of sculpture; and, in the third, their curiosity is the more excited, because no one as yet positively knows for what definite purpose the edifice is intended. To these circumstances may be added one which nowise tends to diminish public astonishment and admiration, namely, that the building is altogether the enterprise of a private individual (Mr. Moxhay), who has shown in it a degree of taste and liberality quite exemplary; certainly an example that we trust will be followed, and, moreover, one that reproaches not a few of our recent structures, both on account of their insignificant character, and the paltry economy manifested in them. With the exception of the *insula* or group of architecture formed by the Athenæum, Travellers', and Reform Clubhouses, the other buildings about town, even of that class, from the "City Club" in Broad-street to the sulky "Oriental" in Hanover-square, are, whatever they may be in regard to internal accommodation, more or less poor and abortive in point of design—the works of mere builders, not of architects. The same remark applies to the offices belonging to many assurance and other public companies. If not the buildings themselves, the designs are for the most part propped up entirely by columns or pilasters, for there is generally nothing else architectural about them; and those might very well be spared altogether, as being not only useless in themselves, but because they become ridiculous affectations when mixed up, as is usually the case, with mean and insignificant features, which are thereby made to look some degrees more mean and trivial than they otherwise would. We have heard it urged as an excuse, that in most cases all the money which can be allowed, or that people choose to allow, for external decoration is swallowed up by columns, so that the rest must be put off with what is more expressively than elegantly termed "a lick and a promise," with a few streakings after "scored pork" fashion for rustication, and a few meagre mouldings to doors and windows. If absurdity be an excuse, the excuse just alluded to is valid enough, of all reason; for why should columns be introduced at all for mere decoration, if for the sake of having them every other part must be deprived of due embellishment, and the whole consequently rendered a maimed, inconsistent, botched-up affair, a ridiculous mixture of the would-be fine and the must-be paltry? We had hoped that the examples of the Travellers' and Reform Clubhouses (more especially as the former has been published as a study for architects,) would at once have clapped an extinguisher upon the miserable "pseudo-classical" system, of which the only recommendation is that it requires no study or invention whatever, but merely *nous* enough to be able to copy columns and antæ from Stuart's Athens, or other publications of the kind. Thus one man's Grecian is just as good as another's; and, with hardly an exception, the mark of the Beast is upon that of them all. Whether Mr. Moxhay's building—which we ourselves have here almost turned our backs upon—will have the effect of now spiriting up others, both professional men and their employers, to emulate his example, is what time must show. In itself it certainly is a very superior specimen, and a far greater public ornament than many of what are called public edifices; which is no great compliment, by the bye, some of the latter being little better than so many public deformities. Perhaps it is well, therefore, for them that it is neither next door or opposite neighbour to any one of them; for even now it puts us quite out of conceit with some of the newly-erected buildings in its vicinity—with the two fire offices at the corner of Bartholomew-lane, and the Wesleyan Missionary Hall in Bishopsgate-street; although if columns—no matter how they may be introduced—are sufficient to constitute grandeur or beauty, the buildings just mentioned possess a decided advantage over the one in Threadneedle-street. The façade of this last is

exceedingly simple in composition, for it consists of no more than a door and two windows on each side of it, between which and the entablature is a deep panel extending nearly the entire width of front, and filled with a relief, the figures of which are little less than the size of life, and not being placed at such a distance above the eye as sculptural decoration of the kind usually is, wherever applied at all, they possess a degree of importance in the design that would be lost were they elevated fifteen or twenty feet higher. Hitherto, wherever sculpture has been introduced at all in the front of a building, it has been either in little bits and patches, or else placed where it cannot be properly seen as a work of art, but merely as ornament and accessory embellishment, valueless and unmeaning in itself, although it may serve to give an air of richness to the architecture. We perceive that there are panels with reliefs in the attic of the front of Buckingham Palace, and that is all that can be seen or understood of them. In such cases there is no situation from which the sculpture can be properly seen, for the nearer we approach the building in order to obtain a distinct view of it, the more are the figures foreshortened, and so far distorted; and almost any scratches and scrawls would therefore answer the purpose as well, either for a near or distant view.

Though the building in Threadneedle-street owes its character chiefly to Mr. L. M. Watson's labours—the author of the noble and poetically-conceived and tastefully-executed piece of sculpture which is now attracting so much attention—it is not without more than usual degree of embellishment in other respects, having a carved frieze and rich cornice. The former, indeed, is not altogether so satisfactory as could be wished, for the *rabesco* or foliage is too stiff and formal in contour; and it is also to be regretted that a little more embellishment was not bestowed upon the door and windows, which now look too plain for the upper part of the front. Still, taking it altogether, this façade is incontestibly one of the most striking, original, and artistic pieces of architecture in the whole metropolis; beyond all comparison superior to those masses of collective littleness or of spun-out common-place, and frigid dulness and meanness which, because they are great, are looked upon as being also dignified and grand.

While the patrician and aristocratic patrons or would-be patrons of art and pretenders to taste do not care to exhibit other architectural taste *pro bono publico* than what may be seen in such spruce specimens of it as Stafford House, and the very neat yet certainly very piddling and anything but dignified mansion of the "Great Duke," or as the brick wall in Duchess-street, which looks like the entrance to a manufactory, or brewery;—while such, we observe, are the architectural specimens exhibited to us by the opulent and the great, a comparatively humble individual—and what is worse, a man in the "city"—one, therefore, in whom it is little less than insolence to pretend to taste at all—has shown a degree of spirit, liberality, and taste, infinitely more creditable to himself and advantageous to the sculptor who has had the opportunity of displaying his talents upon such a scale, than it is likely to prove at all favourable to many other buildings, which now look more paltry than ever, when contrasted with Mr. Moxhay's.

Not the least curious part of the matter is that on this occasion there has been none of that fussiness—generally "much ado about nothing" fussiness—which so frequently takes place; as, for instance, in the remarkably silly business of the Nelson Monument, when, after two *humbugging* competitions, nothing better could or was allowed to be chosen than an overgrown nonsensical column, for which no design whatever was required beyond the mere working drawings. We are afraid, too, it will be found after all that the very best choice of all has not been made in regard to the Royal Exchange,* although the

* Even were that part of the adopted design very much superior in point of design to what it is—at least, if we may judge from the views published of it—the idea of making the Exchange itself—the area where the merchants will assemble and transact business—a mere open court, is so truly preposterous—such a practical absurdity—that we trust it will never be carried into execution. The citizens must be dreadfully afraid indeed of *smotheration*, if apprehensive of being smothered *en masse*, were the Exchange to be covered in. We wonder they do not feel similar alarm at their Guildhall banquets, and instead of talking of a new roof for that structure, do not propose that it

design is certainly superior to the majority of those sent in, and very far superior indeed to the one that, to the utter astonishment of every body, obtained the highest premium!

Equally, or even still more curious is it, that the design for the building in Threadneedle-street is by Mr. Moxhay himself. We do not vouch for the truth of this: it may be mere report, but it has never been contradicted or called in question; and, at all events, there is every reason for believing that, whoever may have made the actual drawings, the ideas for the design are entirely Mr. M's own, the whole being in character altogether different from that observable in any other building about town, and from the manner of any other architect. It is easy enough, therefore, to decide negatively, and say who could certainly not have had any hand in the design. Hardly any professional man would have ventured to propose sculpture upon such an extensive scale, or have thought of making that predominate in the decoration, to the utter exclusion of columns, pilasters, and other usual "*properties*" of architectural composition. Much more likely is it that a "classical" architect would have said—for such was actually the case in respect to one of the designs for the Royal Exchange—that the sculpture might be omitted altogether, without in the least injuring the general character of the building. In the opinion of such a one, a blank panel would produce nearly as good an effect as Mr. Watson's relief. Very rarely indeed does architecture extend any patronage to sculpture in this country, otherwise than as mere heraldry, allowing the sculptor to perform the part of coach-painter, and insert a tiny ducal coronet, or some Gothic armorial bearings and their supporters within the pediment of what is intended for a *Grecian* portico. Of classical sculpture to any extent in this country, we have indeed one example in the series of Homeric subjects which adorn the exterior of the Marquis of Bristol's mansion at Ickworth; and we have now just got another in Threadneedle Street.

Before putting aside our pen, we have to remark that the removal of the French Protestant Church—a very ugly building in itself, although of nearly the same physiognomy as almost all city churches, not excepting the more *admired* than admirable ones by the "great" Sir Christopher Wren—has been attended with a double advantage; for while it has made way for the new building in Threadneedle-street, a new structure for that church is now erecting in St. Martin's Le Grand, on the opposite side of way to and at no very great distance from the Post Office. The style is Gothic, and although small, the building promises to be very far better than almost anything of the kind about town. Such is our impression at present, and we trust we shall have no reason to depart from our opinion, when the building is completed.

THE SPIRIT OF ARCHITECTURE.

It cannot, we conceive, be denied by the most resolute upholder of modern greatness, that architecture has greatly declined among us in these latter ages. The causes of this retrogression have been from time to time pointed out in this journal as due to a want of adventure among architects, and a blind adoration of the architectural forms of Greece and Rome; and these expositions have been received with the incredulity natural to men whose prejudices suggested an opposite doctrine, and who felt that the acknowledgment of architectural degeneracy involved a sort of latent censure upon themselves. We, therefore, propose to go into the subject a little more specifically, with the view of showing that it is the spirit of architecture about which architects ought to be truly solicitous, and that in architecture, as in most other things, the spirit is oftenest and most deeply violated by an indiscriminating adherence to the letter. We shall likewise have occasion to notice the present penury of real architectural skill, and the pernicious influences of the existing modes of practice and

instruction; and we shall venture to suggest the adoption of certain measures, by which these evils might, we conceive, be mitigated or averted. We are too well acquainted with the untractable natures of architects to imagine that any counsel or remonstrance of ours would be much attended to, so long as it might be safely disregarded; but we believe we shall be able to show that architectural art, in the proper sense of the term, is in a very precarious condition, and that unless architects awaken from their lethargy, and do something for its advancement or regeneration, the administration of the art will pass from their hands into the hands of the new sect of decorators, or into the hands of the civil engineers, and architecture, in the ancient and proper meaning of the word, become extinct altogether. We think architects are so obviously interested in preventing such a catastrophe, that they may perhaps give some attention to the means adapted to obviate its occurrence; and we are, therefore, induced to hope that we may be heard with more patience and less incredulity than usual. The subject is manifestly an invidious one, and our remarks, therefore, require much liberality of interpretation; but we rely upon the temper and judgment of those whom the inquiry most nearly concerns—upon the absurdity of supposing that we should derive gratification from being gratuitously censorious—and upon the fact which we, once for all, assert as the key to our observations—that our animadversion is not directed against individuals, but against systems.

And we would, in the first place, remark that whatever architects may think of the present condition of their art, the public opinion is that it never was in a state of greater degradation. This opinion architects may possibly deride: they may look upon public approbation as no evidence of excellence, and public discountenance no test of demerit, and may console themselves for the public alienation by the pleasing emotions they themselves derive from their own combinations and the congenial taste of a few eccentric virtuosi. But we would beg leave to insinuate that it is not for their own gratification that architects ought to work, but for the gratification of the public; not for a little knot of odd and pedantic men, but for the great bulk of mankind; and although architects may affect to despise the popular taste as indiscriminating and uncultured, they will certainly find it much nearer the standard of unperverted truth than any taste formed in the narrow and exclusive circuit of a particular profession. Indeed we look upon the *technical* quality of the taste which architects very generally imbibe as one of the most serious hindrances to eminence in their art. Certain objects become associated in their minds with pleasurable emotion, which in the minds of other men are productive only of indifference or disgust, as anatomical preparations of the brain or intestines may appear beautiful to the medical student, though exceedingly loathsome to every body else. Every profession is apt to create particular bonds of association and particular habits of thought, which it is the aim of all sensible men to exterminate or conceal; and in an art addressing itself to the world at large, any taste deserves to be called bad which is founded upon associations accidental to a particular individual or profession, instead of upon such as are universal and indestructible. Of all errors into which the mere architect can fall, none is likely to be more pernicious than that of being too architectural—of appealing to sympathies which architects alone can feel—and relying upon classical allusions and microscopic graces which to ordinary observers are invisible or insignificant. This is a departure from the spirit of art, and a servile subserviency to the letter; and indeed it will generally be found in copying the forms of ancient structures for modern uses, the deviation from the true principles of art is in the exact proportion of the fidelity of the imitation. To architects who have been long in the habit of contemplating with little less than idolatry these creations of genius, the exact imitation of their peculiar features is likely enough to excite emotions of beauty that will be exceedingly strong; but in the minds of men in general, the prominent sentiment excited will be that such structures are altogether unfit for modern purposes, and as such are ineligible and unattractive. We therefore find that the most celebrated architects since the time of the ancients have been the greatest innovators, and what may seem still stranger, the greatest architects have not, properly

should be unroofed altogether, especially as there are plenty of roofs on such occasions, each guest being provided with the roof of—his own mouth!

speaking, belonged to the profession of architecture at all. Michael Angelo was a sculptor, Sir Christopher Wren a professor of geometry; and we honestly believe that much of their eminence is due to the accident of their having been architectural interlopers. They brought to their new occupation an unsullied taste—extensive information—imagination which had never been frozen by the chill atmosphere of schools—sensitivity which gilded the commonest objects with the rays of its own benignity, and which had communed with the chief aspects of nature, and the most conspicuous objects of the moral and intellectual worlds: and they poured out these accumulated treasures upon their architectural creations, and moulded inanimate matter into images of unspeakable beauty, and quickened it into life by the fire of genius; and while in the course of nature the spirits of these great men have passed away, the reflection of them still exists in their works in all its primitive majesty, and still rules the minds of other men—not by virtue of associations peculiar to any race or generation, but by such as are common to all men in all ages, and are the inseparable concomitants of the qualities by which they are awakened.

There are probably few persons prepared to maintain that there is any architect at the present day equal to those great masters, or that the condition of architectural art is as exalted now as when they flourished. The cause of this declination is, we conceive, chiefly due to the apparent paradox of architects being too solicitously educated; in other words, their education is in our eyes far too architectural. They become thus as it were a separate caste, having few or no sympathies with men in general, and their beauties are such as are not associated in common minds with any interesting impressions. They are, moreover, far too much under the influence of rules and precedent, and attach too much importance to certain recipes of beauty which are administered with too little reserve and discrimination. That there are among architects now living men of genius we do not deny, but what we complain of is, that they can on no terms be induced to exert that genius; they are afraid of ridicule or failure, and instead of producing works of real genius, which we are convinced many of them could do, are content with the reputation of insipid correctness, and ponderous mediocrity. This may, it is true, be a very safe policy for individual practitioners, but is certainly a very spiritless one, and is absolutely fatal to the progress of art; for how can there be improvement if there be not even adventure? Besides, this pusillanimous mode of procedure reduces architecture to a mere trade—a trade, too, of the meanest description, since it does not require even manual dexterity for its exercise. It offers a premium to dullness, by placing stupidity and genius upon the self same terms: reduces architectural proficiency to a simple acquaintance with certain lengths and breadths; and makes beauty a mere question of arithmetical computation, which the artisan is quite as competent to resolve as the artist.

One of the distinguishing features of the present age is love of novelty and of powerful emotion, and if architects continue unable to administer to the popular taste, other instruments will certainly be sought for. Many of the constructions which formerly belonged to architecture have already passed into the province of the civil engineer; and it can scarcely be doubted that all those which require the exertion of science rather than taste for their execution will speedily follow. No one now thinks of applying to architects to build bridges, or piers, or lighthouses, or anything indeed which is not to be embellished. The architects, therefore, it would appear, have already been driven from many of their strongholds: one—an impregnable one—remains with them, and that is—ART. From this position no power can ever drive them, so long as it is defended; but, with a suicidal infatuation that is scarcely credible, they appear of their own accord disposed to abandon it to their opponents. By art we do not mean the power of multiplying Grecian constructions, or of producing columns or gateways which shall be in accordance with the rule, for this the engineer or any one else is perfectly able to do; but we mean the invention of new modes of decoration and distribution answerable to particular purposes, or such a combination of old modes as will constitute in reality a new invention. Except in cases where this is done, the intervention of an architect is altogether superfluous, and if old designs

are only repeated, or repeated with some insignificant modification, architects will cease to be employed; and builders will engage to produce churches or mansions, as ship-builders now produce ships, or engineers steam engines. It appears to us, therefore, to be of the last importance to architects to cultivate assiduously the art of decorative design; not after the formal and prescriptive manner they have observed hitherto, but by means calculated to promote the progress of art, and to awaken the sympathies of the community.

CANDIDUS'S NOTE-BOOK. FASCICULUS XXXIX.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. HOWEVER bad a system of things may be—however flagrant and notorious its abuses—there are always some who are interested in supporting it, and who accordingly set their faces against any reforms in it. Little, therefore, is it to be wondered at that there should be architects who decry competition, and who would fain keep up the old system of architectural monopoly and favouritism, which worked so well for them and their predecessors, and under which they *flourished*—in many cases with the very minimum of talent, the system itself being calculated to suppress all superior talent, by affording it neither chance nor opportunity. Fortunately that system has been somewhat broken down of late years, and the consequence is that some of the "mighty ones" have been thrown into the background and the shade; and now when we look at their works, it is with wonder and regret—wonder how they could have obtained the imposing reputation they did at the time, regret that so many of the fairest opportunities—opportunities not likely to occur again, unless the buildings erected by them happen to be destroyed by fire—should have been recklessly flung away upon them. That competition has its evils and abuses is not denied; highly desirable, therefore, is it—not to get rid of competition itself, but—to check and reform the abuses now tolerated in it. Let us, however, look also at the *blessings* of monopoly and non-competition, before we decide which of the two systems works the best for the art itself, and for the public. In the metropolis alone there has fallen to the share of one monopolist—of one who may well be said to have been *unrivalled* in his profession, for the very sufficient reason that no rivals have been suffered to approach him—opportunity after opportunity, many of which might be called splendid ones. To that individual alone is the metropolis indebted for the following most distinguished architectural ornaments of it, viz.:—Covent Garden Theatre, the Mint, Post Office, British Museum, new centre of the Custom House and its "Long Room," College of Physicians and Union Clubhouse, St. Mary's Church, Wyndham Place, the Library and other buildings in the Temple, King's College (Somerset Place), and the Conservative Clubhouse, besides some others of less note and less importance. With the exception of the first-mentioned—and even that is in very equivocal taste—the rest are little better than so many architectural blanks. When you have said that their columns and antæ are, as far as they and their capitals go, accurate copies from one or two well-known and now rather hackneyed Grecian examples of such members, you have summed up all the merits of the great or we might say the big architect of the big edifices above enumerated. Pity, great pity! that he could not keep the secret of his vast genius and exquisite taste entirely to himself. How many works of pretending dullness and pompous insipidity might we have escaped, had he not met with his copyists in Foulston and others, who have covered the land with their soi-disant classical structures, with their mockery of Grecian porticos stuck on to buildings that in every other respect are of the most John Bullish physiognomy. Most strange it is that with all its rigid punctilio, its servile and superstitious reverence for classical models and precedents, the followers of this school

make no scruple whatever of entirely falsifying the character of Grecian architecture, of running counter to all its principles, and expunging from it all its charm and all its sentiment—all that gives it effect, and all that renders it imposing and impressive.

II. To this most unfortunate school the study of Grecian architecture has most assuredly not proved the torch of Prometheus. Instead of kindling them by its flame, it has only smothered them in its smoke, or its smoke has served to blind the eyes of other people. Some of them may have anatomized Grecian architecture, may have cut up its carcase, and descanted upon the separate limbs and members with tolerable ability; but hardly ever have they been able to tack them together again, except in the most clumsy manner, and then it has still been but a carcase, from which the spirit that once gave it life and grace has fled, and which they are unable to revive by breathing into it a newer spirit, an operation not to be accomplished by a pair of bellows—not even by a patent Vitruvian one.

III. In the efficacy of Vitruvian bellows, however, the Institute of British Architects have, it seems, very great faith, since they have thought it worth while to collect an assortment of them. Surely the Institute must either have a good deal of cash to fling away, or have been bitten with a strange curiosity mania, or it would never encumber its bookshelves with such "venerable lumber" as the different editions of Vitruvius, not one of which, probably, either has or ever will be opened, except to look at its title-page and date. One would imagine that the library must be most abundantly stocked with other architectural works of every kind, because until it was so furnished, a single copy of Vitruvius might be deemed sufficient; more especially as Vitruvius is not so very scarce an author but that a copy of his work may be obtained any day, or even picked up at almost any book-stall. Yet the Institute will have plenty of Vitruvius; it will also have nothing else—or, at any rate, very little more than Vitruvius. Certainly the gaps and hiatuses in its library are many and startling. It does not contain even a set of Wiebeking's works! In fact, to mention what it does not contain would be to make out a list, a bulky catalogue rather, of nearly all the choicest and most valuable architectural publications which have appeared on the continent for the last hundred years, and not a few English ones besides: in short, precisely that class of works which are not likely to be possessed by private individuals—at least, only a very few of them—and to which, therefore, it is all the more desirable and requisite that there should be access in the library of that body which represents the architectural profession.

IV. Arthur Parsey, who is labouring hard to mislead the public, has lately been again advertising, and otherwise doing all that he can to attract notice to his "New Science," for which he has just received a tolerably hearty lashing in the *Atlas*, and has there been called, in very plain terms, an impudent charlatan and quack. It certainly does require more than ordinary mortal impudence to refer, as he has done, to some of the publications which have exposed the utter absurdity of his "*Science*," and its worse than uselessness in practice—or rather its actual impracticability, without even attempting to gainsay any one of the objections brought against it, or to point out the misconceptions and prejudices, if such they be, of his opponents. And although those who have contradicted him with their pens are comparatively few, all the world—at least all the world of artists, are decidedly opposed to him, not even a single individual having adopted the Parseyan Principles of Perspective, notwithstanding that six years or more have elapsed since they were first broached. We all know that prejudice has frequently caused great opposition and mistrust at first, in the case of many inventions and discoveries, that have since been universally adopted. Yet if Mr. Parsey lays "the flattering unction to his soul," that such is the case with regard to his own, he dupes himself far more than he does anybody else. The matter is one which admits of no dispute, for if his "converging perpendiculars" really do produce a more faithful and therefore natural representation of objects, the great improvement attending such system would be as manifest at the very first as at last, because it would, in fact, be self-evident. It is idle to say that artists would still be prejudiced against it, if only because con-

trary to their former practice, too inveterately confirmed to be all at once laid aside. Their refusing to make use of the "*New Knowledge*" could not prevent its spreading elsewhere; their refusing to open their own eyes to the Parseyan "new light" could not hinder the rest of the world from opening theirs and being illuminated by it. If the painters—some of whom seem scarcely to pay any attention at all to perspective—did not care to avail themselves of Parsey's grand discovery, at all events the architects would hardly have failed to do so; and scene-painters would long ere this have certainly turned it to account, and have astonished and delighted the public by such very improved and *natural* mode of representation, more especially for their *bravura* architectural vistas and compositions. However, to give Parsey his due, he possesses both bronze and nerve in a most extraordinary degree; while every body else who understands any thing of perspective laughs at it, he himself stands up undauntedly and be-praises it in his own "lectures" with such rodomontade flourishes as the following (copied from one of them):—"Hail, then, the accomplishment as a British achievement, and let our native talent first reap the advantages of an improved practice." Pity that talent—native and foreign alike—turns its back on Parsey, and refuses to benefit by the advantages he so liberally holds to them.

V. There is, no doubt, some very deep and mysterious meaning in what must strike ordinary eyes as very ridiculous, namely the half white-washed and half tawny face of the building on the west side of Trafalgar Square. Is that "Union" intended as a satire upon Unions generally—both political and matrimonial? The structure certainly looks very much as if spliced together by a modern match-maker—a fashionable specimen of the compound creature termed Man and Wife. After all, the greater probability is, that there was neither satire nor joke in the matter, but that the odd diversity of complexion in the building arises from the "Club" contenting themselves with *compo* for their portion of it, while the "College" would have theirs of stone. Why, then, some inquisitive folks may ask, did not the architect proceed accordingly, and make the two buildings two distinct designs, instead of passing them off for a single one dressed in a motley suit?—A puzzling question! to which the most likely answer that can be given, is, that he thought it good economy to make one design serve for both, and to kill two birds with one stone.

VI. The world has had didactic poems upon almost every subject. The "Art of Cookery" has found poets to chaunt its praises and its precepts, as well as the "Art of Poetry" itself; but I do not believe that any poem upon architecture exists in any language; at least I have been unable to discover even the title of such production. And yet, methinks, the subject is one of which very much might be made in poetry. What visions of gorgeous splendour does even the very name of the Alhambra conjure up! How awful, sublime, the eternal cavern fanes of India, and the massive and many-pillared structures of Egypt. Persepolis, Palmyra, Baalbec, Ionia, Greece, the Roman and the Goth, all throng around the bard, and court his strain! But come, this is sheer rhapsody and frenzy, easily abated, however, by a dose of—Smirke. So far from being inclined to patronize poems on the art of architecture, many architects seem never to have read that of Horace on the Art of Poetry, from the first lines at least of which they might, *mutatis mutandis*, learn something, as haply the following paraphrase may show:—

Should some odd painter lovely Venus draw
In judge's wig and grave costume of law;
Or deck some legal sage in Cashmere shawl,
And feathered bonnet, how you'd stare and squall!
You'd think him mad; and fair ones cry, "Oh dear,
How droll! how monstrous! how absurd! how queer!"
You'd laugh; yet why?—not more absurd such dress
Than many a "classic" architectural mess,
Where nought agrees—no part another matches,
But all's made up of motley shreds and patches:
A daw in feathers—peacock here, there goose;
"Splendid but neat," magnificent yet spruce;
And pert as spruce—more paltry than refined,
With front all foppery, and all rags behind.

Poets and painters may invent, we grant,
 So, too, were their invention not so scant,
 May architects; yet not play such queer tricks,
 As tack Greek columns to a box of bricks;
 With Parthenon for model, build what looks
 As if just sent home from the pastry-cook's;
 Crowd Roman porticos with London sashes,
 Or show such doggrel taste as was great Nash's.

LITHOCROMY.

Report of the Committee appointed to examine the Elgin marbles, in order to ascertain whether any evidences remain as to the employment of Colour in the decoration of the Architecture or Sculpture. Read by W. R. HAMILTON, Esq., Honorary Fellow, at the closing ordinary Meeting of the Session 1836-7, held Monday, 24th July, 1837.

(From the Transactions of the Royal Inst. of Brit. Architects.)

COMMITTEE appointed by resolution passed at the ordinary meeting held Monday, the 5th December, 1836, to examine the Elgin marbles in the British Museum, in order to ascertain whether any evidences remain as to the employment of colour in the decoration of the architecture or sculpture, and to report the result of their examination.

The Committee to consist of W. R. Hamilton, Esq. Foreign Sec. Roy. Soc. of Literature; R. Westmacott, Esq., R. A.; C. L. Eastlake, Esq., R. A.; C. R. Cockerell, Esq., R. A., Hon. Fellow; Dr. M. Faraday, F.R.S., Hon. Member; and Messrs. Angell, Donaldson, and Scoles, Fellows.

ELGIN ROOM, BRITISH MUSEUM.—At a meeting held on Tuesday, the 13th of December, 1836; present, R. Westmacott, Esq., R. A.; C. Eastlake, Esq., R. A.; Dr. Faraday; Messrs. Angell, Donaldson, and Scoles; as also Messrs. Forshall and Hawkins, officers of the Museum; T. L. Donaldson stated that Messrs. Hamilton and Cockerell, being at Cambridge, had written to say they could not attend.

The attention of the Committee was first directed to fragments Nos. 127 to 130 inclusive, in black, being Nos. 252 to 255 red, portions of the Ionic antæ capital and continuous mouldings of the hexastyle portico of the Erechtheum. The object was to ascertain whether the inequalities of the surface of certain portions of the plain faces arose from a coating of some substance originally placed upon the surface of the marble, for the purpose of receiving the colour or paint, or whether it resulted from the action of the weather.

It appeared, upon examination by a powerful glass, that the raised portions, which remained in some parts, and which had a deeper ochrish tone than the rest of the marble, was the original surface highly polished, and that the general surface of the marble had been pretty equally worn away to the depth of about $\frac{1}{16}$ part of an inch by corrosion.

The ochrish tint also seemed the result of the weather, as upon examining portions of this and other blocks of marble which were broken, the fractured surface presented in some parts a like colour, produced evidently by the action of the weather, or other accidental circumstances, such as contact with the earth, &c.

The committee then proceeded to examine the fragment marked No. 154 in black, and No. 260 in red; No. 260 being a portion of one of the beams of the propylea of the Acropolis at Athens. The fascia presented evident marks of coloured meandering ornament, and upon washing the surface the outlines of the meander were found to be marked or indented with a sharp tool. The whiter part has the surface polished, but the surface of the darker portion is rough. The committee could not decide whether the darker tone resulted from the stain produced by the atmosphere, or rather the dust and dirt of the air, which would adhere more to the rougher surface of the marble, or whether it arose from the original application of paint or colour; but the presumption is in favour of the atmosphere or dirt, as the dirt or colour readily washed off with a sponge.

The committee were unable to decide whether the parts now

smooth and rough were originally in that state, or whether the part now rough has become so in consequence of the action of the atmosphere upon it, the smooth part having been protected from that action by gilding or colour.

No. 308 in black, now 131 in red, at the north end of the Elgin room, and upon which the capital from the propylea of the Acropolis of Athens is placed, is a larger fragment of the same part of the propylea as No. 260, and the ogee bed moulding is preserved entire, with the leaves distinctly apparent on the surface. Upon being moistened with a sponge, it was evident that the outlines of the ornamental leaves and stems were engraved with a tool,* and that the darker parts of the ornaments were rough on the surface.

Sarti the modeller being present, who has been employed for many years by the trustees of the British Museum, being now engaged in taking moulds of the whole series of the Elgin Marbles belonging to the Parthenon, stated to the committee that he had never been able to discover traces of paint or artificial colour on any of the figures of the bas-reliefs, metopes, or sculptures of the pediments, although his attention having been originally drawn to the subject, he had carefully examined every portion of the surface of each figure, for the purpose of ascertaining whether any traces or signs of colour were to be found. He stated also that the whole surface of the marbles had been twice washed over with soap leys, subsequently to their having been moulded on former occasions, as that or some strong acid is necessary for the purpose of removing the soap which is originally put on the surface in order to detach the plaster of the mould. Dr. Faraday was of opinion that this circumstance was of itself sufficient to have removed every vestige of colour, which might have existed originally on the surface of the marble.

The committee then proceeded to examine two Athenian tiles in Room VI. of the Townley Collection, their attention being directed to them by Mr. Hawkins.

They are of terra cotta, covered with a thin coating of fine stucco, the surface of which is decorated with the meandre, and honeysuckle, and lotus-leaved ornament. The surface being moistened with a wet sponge, three different colours were perceptible, a white (or tone of the ground or plaster), green of a darkish untransparent tone, and a deep red in small portions, of unfrequent recurrence in the pattern or composition.

It occurred to the committee that where these architectural enrichments were employed in large quantities, it is probable that the mode of forming them might have been similar to that adopted by decorators at the present day, known by the term stencilling. The fragment in question was hardly of sufficient length to enable the committee to decide whether this method was adopted, or whether the enrichment was done by hand.

1st June, 1837.—At a meeting of the committee held in the Elgin room of the British Museum, present, Messrs. Hittorf, Hamilton, Westmacott, Angell, and Donaldson, the minutes of the previous meeting were read, as also the following letter:—

Atherstone Hall, April 17, 1837.

"Mr. Bracebridge is happy to forward a memorandum of patterns and colours from the Erechtheum; they are drawn from the northern portico of that conjoint temple of Minerva Polias, Pandrosus, and Erechtheus, so well known in the Acropolis. This side of the temple, being so well sheltered from the sea breeze, has presented its sculptured ornaments as fresh and sharp as if lately finished; and the columns of this portico being fluted with capitals elaborately worked and well sheltered, have retained remains of colour. At the top of the flutings especially, a thin coat of slate-coloured paint is visible, at other points yellow and red color may be traced; but the remaining pieces are so small, and the colours so much faded, as to leave the subject in dispute; this being alone certain, that there was colour once carefully applied (at all events to the intaglio parts of the relief

* Might not this mode of engraving the outline have been for the purpose of preventing the colour from spreading beyond the pattern, as well as for giving a sharp and distinct outline to the ornament?

or concave parts of the capitals, &c.), and that this colour was of various shades; the protuberant part of the work retains no colour. The probability that blue, red, and yellow were used is very strong. Some portions of paint might be chipped off and subjected to analysis, which would determine what there is, in truth, but little or no doubt of.

"Mr. Bracebridge has not examined the capital in the temple of Theseus, said to bear marks of paint, but he believes much the same could be said of it as above of the Erechtheum.

"In the winter of 1835-6, as Mr. B. has stated in his letter to Mr. Wordsworth, printed at the end of 'Athens and Attica,' an excavation was made to the depth of 25 feet at the south-east angle of the Parthenon; here remains were found of huge blocks of marble fresh from the quarries, chippings, &c.; and below these, fragments of vessels, pottery, and burnt wood. No one who saw these could doubt that a level was dug down to below that where the workmen of the Parthenon had thrown their refuse marble, in fact the level of the old Hecatompedon, of which possibly the burnt wood may have been the remains. Here were found many pieces of marbles, and among these fragments parts of triglyphs, of fluted columns, and of statues, particularly a female head (the hair in nearly the costume of the present day). These three last mentioned fragments were painted with the brightest red, blue, and yellow, or rather vermilion, ultramarine, and straw colour, which last may have faded in the earth.

"These curious specimens are carefully preserved in the Acropolis, but much fear is entertained of their retaining the brightness of their highly contrasted colours for any length of time. The colours are laid on in thick coats. The female face had the eyes and eyebrows painted. When we consider the brilliancy of Pentelic marble when fresh worked, there appears a reason for using colours beyond that of imitating the usages of Attica in more ancient temples, namely, that the minuteness of the work in many parts would have been lost to the eye amidst the general brilliancy."

Mr. Donaldson informed the committee, that having in his possession various portions of coatings taken by him from several buildings at Athens, he had forwarded them to Dr. Faraday, Hon. Member, with the request that he would be pleased to furnish the committee with his opinion upon the composition of such portions of coatings; to which he had received the following reply.

"Royal Institution, 21st April, 1837.

"MY DEAR SIR—I return you the box, with the remains of the samples.

"A. Portion of coating taken from the antæ of the Propyleum. The blue produced by carbonate of copper: wax being mingled with colour.

"B. Portion of coating taken from the soffits of the metopes of the Theseus. The blue is a frit or vitreous substance coloured by copper. Wax is present here.

"C. Portion of coating taken from the columns of the Theseum. I am doubtful about this surface. I do not find wax or a mineral colour, unless it be one due to a small portion of iron. A fragrant gum appears to be present in some pieces, and a combustible substance in all. Perhaps some vegetable substance has been used.

"D. Portions of coatings from the caissons or lacunaria of the Theseum. The blue is a copper frit or glass, with wax.

"E. Portions of coating from the northern wing of the propylea. The colour, a carbonate of copper. Wax is present.

"F. Ditto, ditto (north wing propylea), as E.

"I also return you the drawing and the letter.

"Ever truly yours,

"T. L. Donaldson, Esq. &c. (Signed) "M. FARADAY."

In order to ascertain whether a portion of the surface of the statues of the Fates, which presented an ochreous tint and a more glossy surface than the other parts, was due to some foreign matter artificially applied to the surface, some parts were peeled off easily from the back of one of the figures on the application of a penknife. These were also submitted to Dr. Faraday, who reported as follows.

"Royal Institution, 8th June, 1837.

"MY DEAR SIR—The particles you sent me seem to have come from a prepared surface. Being put into a dilute acid, a portion of adhering matter is dissolved, and the principal portion is left in an untouched and cleaner state. Being then washed and dried, it is found that this consists of carbonate of lime and a combustible substance which protects the carbonate from the acid. This combustible substance when heated is destroyed, leaving charcoal, and then acid can attack the calcareous matter. The combustible substance may perhaps contain wax, but it does not present undeniable traces of that body. It is in small quantity as compared with the wax present in Mr. Donaldson's specimens. There is no mineral colour present in the particles, except it may be a small portion of iron colour, and that I rather judge to be accidental. Whether or no any animal or vegetable colour had been used is more than I can say.

"I am, dear Sir,

"Very truly yours,

"W. R. Hamilton, Esq. &c. (Signed) M. FARADAY."

The secretary also submitted to the committee various portions of glass eyes, which he had taken from the torus between the volutes of the Ionic columns of the tetrastyle portico of the Triple Temple in the Acropolis of Athens. They are of four various colours.

On this occasion also M. Hittorff, having a series of drawings of his restoration of the Temple of Empedocles at Selinus, restored by him and coloured in its several parts according to his opinion of the polychromatic system as applied to architecture, favoured the committee with a full explanation of the grounds upon which he had applied colour to the various parts of the edifice.

The committee then proceeded to examine the several marbles alluded to in the first report, and were satisfied with the accuracy of the former observations of the committee.

Upon a consideration of all the facts contained in the preceding minutes, it appears to the committee, that there remain no indications whatever of colour artificially applied upon the surface of the statues and bas reliefs, that is, upon the historical sculpture. That, according to Dr. Faraday's opinion, those portions of the marble which from the tone and surface might be supposed to be the result of colour applied thereon, are the original surface of the marble stained by the atmosphere, the presence of iron in the marble, or by some such natural cause. That some of the architectural fragments present indisputable traces of tone indicative of regular architectural ornaments, and that the outlines of such ornaments are distinctly traceable, being marked with a sharp instrument upon the surface of the marble. The committee cannot positively state, from the appearance of the marble, that such tones have been produced by colour, as they think that none of the colour itself remains, but that the indication of tone results from mere variation of surface. Judging, however, from the information contained in Mr. Bracebridge's communication, there appears no reason to doubt that colour has been applied. This is confirmed by the portions of coatings brought from Athens by Mr. Donaldson and analyzed by Dr. Faraday, who has detected frit or vitreous substance and carbonate of copper mixed with wax and a fragrant gum. This analysis proves that the surface of the marble of the shafts of the columns of the Theseum, and other parts of the edifices from which these specimens were taken, were covered with a coloured coating. The glass eyes also of the Ionic capitals of the tetrastyle portico in the Acropolis at Athens prove, that various materials were employed by the Athenians in the decoration of the exterior of their marble buildings.

But although the statues and bas reliefs of the Parthenon, at least those portions of them preserved in the Elgin collection, do not afford any evidence of the use of colour, yet there is a constant repetition of small circular holes in the horses' heads and manes, and in one hand of each rider, showing that there had been originally bridles and straps to the horses, either of metal, leather, or some other similar substance. Similar holes are perceptible in the statue No. 94 (in red) of Proserpine, one of the two female figures of the eastern tympanum of the Parthenon, called also the Seasons or Hours; they are in the

arm just above the wrist, apparently for the purpose of attaching bracelets, and in the shoulders at the junction of the drapery, as though a metal rosette had been affixed there. On the neck of one of the Fates No. 97 (in red) are also two noles, which seem to have been for a necklace. In the back of the torso of Victory No. 96 (in red) are large holes, in which it is supposed bronze wings were fastened. No. 101 (in red) is a fragment of the upper part of the head * of Minerva; the sockets of the eyes are hollow, and were evidently filled with metal or with coloured stones, and holes remain in the upper part of the head, affording the presumption that there was originally a bronze helmet attached to the marble. The angles of the *Aegis* of No. 102 (in red), which is a fragment of the statue of Minerva, one of the principal figures of the western pediment, are drilled with holes, by which the metallic serpents were attached, and in the centre a head of the Gorgon.

THOMAS L. DONALDSON, Hon. Sec.

THE ARCH IN ARCHITECTURE, ITS ORIGIN, FORMS, AND PROPORTIONS.

THE oblique arch having so prominently occupied the pages of the *Journal*, there being ten papers on that subject, and only one on the arch itself, by Mr. Frederick East, Vol. 2, page 354, has induced me to offer a few observations. Mr. East states, on the authority of Livy, Virgil, Herodotus, Ktesias, and Strabo, that, probably, the arch was instrumental in the construction of the hanging gardens of Babylon, built B. C. 1200; but that certainly the arch was known in Assyria, as also in Lydia, which latter country was subdued by the Babylonians about the period above mentioned; and with respect to the Roman works of the "*Avaca maxima*," said to be commenced by Tarquinius Priscus, and finished by his grandson Tarquinius Superbus, 7th King of Rome, Ferguson in his *Roman Republic*, hints that they may be the relics of some city previous to the erection of Rome. From these authorities there can be little doubt but that the arch was in familiar use at an early period, but unknown in Greece till within a century of the Christian era.

This subject engaged my attention several years ago at a very early age, in consequence of the prominence given to the five orders over the arch, which, in my humble opinion, was worthy of a more prominent place; the only works known to me at that time solely devoted to it, being, a treatise published in 1772, by Dr. Charles Hutton, and Attwood on the construction and properties of arches; since that the following authors have come to my knowledge:—Semple, Telford, Ware, Smeaton, Milne; and of foreigners, French—Perronet, Gauthier, Borsland, Bruyere, and Belidor; and of Italians—Alberti, Palladio, and Serlio. First let us consider what an arch is; the term is derived from the Latin *arcus*, a bow, and has been defined to be a concave structure raised upon a mould called the centreing, in the form of the arc of a curve, serving as the inward support of some superstructure; also as part of a circle less than a semicircle; as a hollow building raised upon a mould in the form of a semicircle; as a contracted vault; and as an artful disposition of stones generally in a bow-like form, by which the weight produces a mutual pressure and abutment, so that they not only support each other and perform the office of an entire lintel, but may be extended to a great width, and made to carry the most enormous weights. There being no word in the Greek language meaning an arch, it is inferred that the object was unknown, although it has been said that the pediment of the Greeks suggested the arch, and it has been found in the Temple of the Sun, at Athens, and of Apollo at Dydamus, concealed in the walls, covering the necessary openings, perhaps similar to discharging arches as now used by the moderns. In sacred history the arch is

first mentioned in Ezekiel, chap. 40, v. 16, in his description of the Temple. "There were narrow windows to the little chambers, and to their posts within the gate, round about, and likewise to the arches, and windows were round about inwards, and upon each post were palm trees." B.C. 574. The bridge over the Euphrates, at Babylon, Herodotus expressly says, was built on stone piers bound with lead, and lintel or squared beams of timber. The tunnels also at Babylon, mentioned by Diodorus Siculus, were probably covered in the same way. Visconti, on the authority of Plutarch, assigns the invention to Alexander himself, who lived B.C. 323, or about a century after Herodotus; Dr. Pococke thinks the Egyptians were unacquainted with the arch, although Belzoni found Egyptian arches at Thebes, and one at Gouinon, leading to the valley of Beban el Malook, and Diodorus Siculus, in describing one of the celebrated buildings of Egypt, takes particular notice that it was tipped with one stone; Sir John Chardin, in describing the subterranean passages at Tobelminar, does not in any way allude to the arch, a circumstance he would not have omitted if it had been the case; one tomb is said to be arch-roofed, but it is in solid rock.

The Romans have the merit of being the first to introduce the arch into general use. The earliest on record is the conduit at Tusculum near Rome, 16 ft. wide, and 30 ft. high. The second, the theatre of Marcellus at Rome, built in the time of Julius Cæsar, where semicircular arches are found, and I think it may with truth be said, a genuine arch did not exist prior to the time of the Romans. With the remarks of your former correspondent I agree, that the arch was not known in Greece, and I think there is doubt of its being used at Babylon, or Assyria, or in Rome, earlier than the time of Cæsar, B.C. 50. In the quotation given from Ezekiel, it appears to me that the true arch is meant, as the impost was the earliest ornament in arches of stone, and that, too, with leaves resembling those of the palm. This would place the invention nearly 500 years previous to the time of Cæsar. Again, the absence of any remains is a great obstacle to the latter conclusion, so that we must be content to allow the merit to the Romans of bringing the arch into general use, but the extent of its application was reserved for modern times, as Waterloo, London, Gloucester, and Chester Bridges amply testify.

There are the following forms of arches in use; the date of their introduction is almost as uncertain as the origin of the arch itself:—

- Tudor Arch, called after the name of the reigning family.
- Arched Dome, which arose in Etruria.
- Semi, or Roman, in exclusive use until the 12th century.
- Horse-shoe, or Moorish, more than a semicircle, found in East Morgan, a building of the Anglo-Normans.
- Elliptic, first found in the tower of the Deanery of Lincoln, 1500.
- Inverted Arch, found in Cathedral of Wells and Salisbury.
- Catenarian, or Arch of Equilibration.
- Scheme or Skene, or Imperfect Arch, less than semicircle.
- Hyperbola, and Parabolic, from sections of a cone.
- Trochoid, or Cycloid, invented by Descartes, 1615.
- Epicycloid, formed by motion of a point in a paddle-wheel of a steam boat, a combination of circular and progressive motions.
- Pointed Arch, first occurs in church of Friendsbury, built by Paulinus the Sacrist, 1137; called also the Saracenic Arch. Supposed to be introduced from the Crusaders, although more probably it took its rise from the intersection of two circular arches, called interlacing, an example of which is in Kelso Abbey.

There are 22 varieties, drawn from four, six, and eight centres.

Straight Arch, or Plat Band, with joints converging to a common centre, an example, Lincoln Cathedral and Greenwich Hospital.

Vaulting or Groins, the latter arises from the intersection of the former, about the 14th century.

Rampant or Flying Arch, used to connect buttress and pinnacles with the main building.

Having stated as much as I can learn as to origin and different forms of arches now in use, the most important part of the inquiry remains—the proportions of the arch in its adaptation to bridge building; the different forms, as circular, segmental, and elliptic, must

* This fragment alone may perhaps be considered as an exception to the previous statement, that no evidences of colour existed on the statues or figures of the Parthenon. The hair appears to have a red tint, which becomes distinctly apparent upon the application of water.

be considered more as dependent on situation. The proportion of parts has generally been estimated in parts of the span or chord, and $\frac{1}{15}$, $\frac{1}{10}$, up to $\frac{1}{4}$, has been stated as the proper depth for the voussoirs at the crown or apex—the thickness of abutment $\frac{1}{4}$ of the span, and of the piers $\frac{1}{2}$. The rise or versed sine should not in any case be less than $\frac{1}{4}$ of the chord. When the height of the piers exceeds the rise of the arch, an addition of $\frac{1}{4}$ (if their size be estimated by the previous standard) is made to their thickness, and when the span of the arch exceeds 50 feet, it is usual to increase the voussoir, as the abutment or skewback is approached. The success that has attended Mr. Brunel's bold experiment of the Maidenhead Bridge, carried into successful execution amid the sneers and jibes of his compeers, in the application of brick to a span for which, a few years ago, no stone save granite was considered competent, augurs favourably for the use of arches of brick to an extent never before contemplated, especially where high banks offer the additional inducement to try the effect, there being then no approaches to make. The Maidenhead Bridge is turned in half-brick rings in cement, 5 ft. 3 in. in depth at the Crown, and 7 ft. 1½ in. at the springing; the two main arches are elliptic, and 128 ft. span, with a rise only of 24 ft. 3 in.; the land arches are 21 ft. and 28 ft. span, there being six of the latter on one side and two of the former on the other. The immense mass of 7 ft. in depth of brick in the arch is, in my opinion, the true source of security.

The proper position of the joint in complex figures, such as the ellipse, parabola, and cycloid, is a good exercise in geometry; the position of the joint should be perpendicular to a tangent at that point. I feel confident that arches of stone might be constructed twice their present extent as regards span; there would be no danger of compression of the materials, as the cohesive power per square inch of granite, sandstone, and Bath stone, are respectively 2800, 896, and 755 lbs, the weight per cubic foot of each material being 173, 144, and 92 lbs.

Newcastle-upon-Tyne.

O. T.

The following works have been consulted:—The C. E. & A. Journal; Elmes on Architecture; Woodward on the Wisdom of the Egyptians; Sir James Hall's Origin of Gothic Architecture; Stuart & Rivet's Athens, and Stuart's Dictionary; Papers by Stukely, Gunn, and Sir H. Wotton, in the London Archæologia.

NOTES ON STEAM NAVIGATION.

Holding down bolts.—Those which go through the bottom of the ship, if of iron, are very quickly eaten away. It is a usual and beneficial practice to tin them before they are inserted, but even in this case they do not last very long; the tinning is probably in most cases injured in driving the bolt: zincing would be better. When the vessel has much rise of floor, and the keelsons are consequently very deep, and the bolts therefore very long, it is often very inconvenient to get the bolts introduced at all, especially if the vessel draw much water; for the blocks upon which the vessel has to be placed in the dock require to be very high, and when high there are few docks in which there is a sufficient rise of water to enable the vessel to surmount them. It has, therefore, been found expedient in some cases to make the holding-down bolts with a nut at each end, and to reeve them from above; but in such cases it is almost indispensable that the bolts should be of copper or Muntz' metal. If of iron the threads of the screw would be soon worn away, or the nut would get so fixed by corrosion that it would be very difficult to get the bolts out when they required to be renewed. Holding-down bolts of the common description last from three to five years, but if made of copper or Muntz' metal, they will last as long as the ship. Those holding-down bolts which go through the keelson merely with a notch cut upon the under side of the keelson for the reception of the nut, waste away more quickly than those which go through the ship's bottom. As a general practice

the best plan is to make twelve bolts go through the bottom in each engine, four at the crank framing, four at the cylinder, and four at the main centre; and these bolts should be of copper or Muntz' metal, with screws at both ends. The rest of the holding-down bolts should be of iron, and should not go through the keelsons, but be screwed into them, as wood screws, by means of a square neck, and be furnished with a screw and nut above. It is of course necessary that the threads of the bolts screwed into the wood should be wood screw threads, and the bolts themselves should have considerable taper.

Expansion Valves.—Slide expansion valves are, in our opinion, the best, yet they are very little used; probably from the difficulty of obtaining a good combination for altering the degree of expansion; yet such a combination is, we conceive, attainable enough, and there are already several exquisite contrivances of Mr. James Whitelaw's which go far towards the removal of the difficulty. Of the double-beat description of expansion valves, that description is extremely objectionable which has two discs of brass upon one spindle, fitting into the upper and lower valve seats, situated in an upright pipe. Such valves can never be tight except by accident:—if tight when cold, they cannot be tight when hot, for the spindle being surrounded with steam, will expand more than the pipe in which the seats are situated, which has steam only on one side, and which is, moreover, generally of cast iron, the spindle being of brass. The double-beat Cornish valve is the only species of double-beat valve that should ever be employed. Messrs. Fawcett, of Liverpool, have, in some cases, applied a single-beat valve for expansion, with perfect success. It would, of course, be extremely difficult to open this kind of valve, but for the combination of levers, or rather the principle of the combination, used in Mr. Watt's original valve gearing; but Messrs. Fawcett have greatly simplified that arrangement, the proper action being produced by means of a single crank.

Heat.—It cannot be doubted that combustion would be rendered much more perfect in steam engine furnaces if the incandescent fuel, instead of being surrounded with water, which, by a rapid absorption of heat, depresses the temperature of the fire, were surrounded by some substance which would prevent the heat from being abstracted by conduction, thereby rendering the heat of the fire the greatest possible under the existing conditions. But it becomes a question whether if by lining the furnaces with fire brick, and thereby preventing the heat from being carried immediately from the furnace into the water, the same amount of beneficial effect would be obtained as by the present practice; and this question resolves itself into the still more abstruse one whether heat is a material substance or a mere property of matter. If heat be a material substance, whatever heat is not given out in the furnace will be given out in the flues, supposing the temperature of the chimney to be uniform; but if it consist in mere vibration, either in the particles of bodies or any ethereal fluid pervading them, we may suppose the possibility of those vibrations so counteracting one another as to subside or cease without the production of any adequate effect upon material substances. Sound, it is well known, consists in the vibration of the air; and it is further known that two sounds may conspire to counteract each other's effects, and actually produce silence. Two rays of light, in like manner, may be so managed as to produce darkness; and may we not, in like manner, imagine the possibility of two rays of heat producing absolute cold? It is not impossible that in all furnaces such neutralization may take place, in a greater or less degree; and it is not at all consequential, that by making the combustion more perfect in the manner we have indicated, a greater available heat will be produced. The subject is indeed involved in much uncertainty: it is a very important subject, and we beg leave to recommend its investigation to those who have time and opportunity for experimental researches.

Engine Frames.—We think the adoption of the Grecian or Gothic orders of architecture in the cast iron work of steam engines, is an evidence of bad taste; but the rejection of every species of embellishment is worse still, being indicative of the want of taste altogether. The beauty of a piece of machinery is, in our eyes, a point of no trifling moment; a handsome engine will always be better taken care of and

more cleanly kept than one not so distinguished; it will realize a higher price if sold, and need cost little if anything more in the first production. We would not, it is true, sacrifice any useful quality to embellishment, nor would we purchase beauty at any great expense; but we think it extremely desirable that the patterns for the cast iron work of machinery should be so made that, whilst securing the most attainable degree of fitness, they will, without any great additional trouble, confer the additional quality of beauty. We know that there are those who maintain that beauty consists altogether in fitness, and that that object is the most beautiful which possesses every physical property necessary for its intended uses, and nothing more; but this is so preposterous and puerile a heresy that it scarcely merits confutation. A Corinthian column would be quite as fit for supporting its superincumbent weight, if reduced to a mere cylinder of stone; but would it then be as beautiful? The dusky plumage of the sparrow forms as efficient a defence against the weather's inclemencies as the metallic splendour of the humming-bird, and the humblest productions of our looms as effectual habiliments as the gorgeous fabrics of Damascus, or the choicest productions of Cashmere. Fitness is indeed in most things one of the most conspicuous constituents of beauty, but it is one only of a great number, and not always the one which most prominently interests us; and although there are men of such cold imaginations and lethargic sensibilities as to disenable them to perceive beauty in objects except in the ratio of their fitness for a specific purpose, yet such men are only exceptions to the order of nature, and are as surely of a defective constitution as those who are unable to relish the delights of harmony in consequence of the want of a musical ear. The pleasure we derive from the contemplation of the works of Nature is not in many cases due to any sense of fitness. The spectacle of a mountain landscape does not awaken the sentiment of beauty from any specific configuration of the cliffs, or any distribution of the rocks and rivers connected with ideas of fitness, but by virtue of the sympathy with sentient beings associated with the perception of those objects, and which appeals to the judgment but to the imagination and the heart. The rugged mountain which starts abruptly from the vale—the eternal snows which crown its summit, and pour from their bosom innumerable cascades, and the giant fragments, grey with age, that are strewn about its base—fathomless and impassable ravines, through which the waters foam and wrestle, like an angry and imprisoned maniac—cliffs overhanging and inaccessible, where the eagle reigns in solitary majesty—and echoes which repeat the roar of the cataract and the sighs of the rising tempest—these are all admitted to be beautiful, but it is sympathy alone to which their beauty is attributable, and which gives them life and interest. Without it the sublimest landscape would no more affect us than any casual assortment of colours on a painter's palette.

The ruling appetite of human nature is love of sensation, and nothing is capable of making us feel deeply but the fortunes, past, future, or possible, of man, or at least of some sentient being. Objects do not possess any property in themselves capable of exciting the sentiment of beauty, but interest us only by their capability of reflecting emotions associated with them; and that man will relish beauty most strongly and perceive it most readily, whose imagination is most lively and whose social affections are the most fully developed. The beauty of material objects being merely the reflection of emotions pre-existing in the mind, no beauty will be perceived where those emotions do not exist; and those emotions are so nearly akin to benevolence, that a love of beauty is justly held to be symptomatic of an excellent heart, and those whose taste is inanimate or perverted, are, not without reason, suspected to be persons of a low morality, especially in its finer gradations. Good and sensible men cannot regard the quality of beauty as unimportant to any object, and will advocate its creation in all cases where great expense would not be the consequence; and in the frames of steam engines where it may be attained so easily, we think there are few who will advocate its rejection. There is a species of decoration answerable to steam engine frames, or rather an infinitude of kinds, which would confer a high degree of beauty, not by the use of any of the existing archi-

tectural orders, which will create associations which must end in disappointment, but a species of embellishment proper to this specific purpose, and such as to be susceptible of adaptation to all the shapes which science indicates as the fittest for resisting the strains to which the framing is subjected.

ON PAINTING TIMBER.

WE extract the following observations on painting timber when exposed to damp, by Mr. Lander, from the Professional Papers of the Royal Engineers.

"I beg leave to lay before you a few observations which I have made on the construction and causes of decay in bridges, on the works at Devonport, having been employed on the erection of the bridge at the north-west barrier in the years 1812 and 1813, and also on a large repair in 1837; and I am now employed on a similar repair at the north-east barrier bridge, which, I think, was built in 1816, which has induced me to make the following remarks:—

"1st. These bridges were paved with Guernsey pebbles, which, I think, was one cause of decay, as the wet constantly dripped through the joints; an evil which may be avoided by macadamizing, by which such a compact body is formed that the wet cannot get through, and the joists and girders, &c., are thereby kept perfectly dry, besides the advantage of the vibration being very much reduced, as is the case now at the north-west barrier.

2nd. The whole of the wood-work below, as well as the under side of the flooring, was frequently payed over with coal tar, which, forming a thick body on the surface, was another, if not the greater cause of decay, as it completely prevented the air from acting on the wood, thereby keeping all moisture within, which of itself is sufficient to decay it. It must be observed that the plank or flooring was so rotten, that in many places it would not bear the weight of the men to work on it, and many of the joists and girders broke into two or three pieces in removing them: some of them were found to be quite dry, and in a similar state to snuff.

3rd. As a further proof of the bad effects of paying and paving bridges, I may state that the bridge at the south-east barrier across the old works leading to Stonehouse, the girders, joists, &c. of which have never been payed or painted, and the road above always macadamized, remains sound and good at this time; and I know this to be a much older bridge than either of the former.

4th. I should state that the timber alluded to above is oak, but I think the same observations will apply to other timber, and in other situations, such as fences; for many posts and rails of the stockade fence here have frequently been found decayed, while in other and older fences, although much worn by time, yet not having been payed or painted, the fibre of the wood remains in a healthy state.

5th. I am also of opinion that skirting to walls, and linings to store-houses and other buildings, if not painted, would last much longer, as the damp from behind would then be allowed to evaporate by the action of the external air.

PROFESSIONAL BEQUEST.

SIR—The following information deserves to be more generally known to the public, and particularly to the profession, than I believe it to be; and no way occurs to me more likely to attain that desirable end than the notice of it in your journal, which, as it is especially dedicated to whatever concerns architecture and surveying and their professors, is a very suitable medium for giving it publicity.

By the will of Mr. George Jernegan, of Hatton Garden, himself in the profession, dated the 28th November, 1812, and proved in the Prerogative Court of Canterbury in 1816, the following bequest, *inter alia*, is made, viz., after stating "Ten pounds per annum in perpetuity I present to my two executors, viz., 5*l.* each, for their attendance and trouble, in seeing to the final adjustment of these concerns," the will proceeds "the residue and remainder of interest in the 3 per cent. Reduced Annuities, I wish to go towards the support and comfort of some worthy character bred a surveyor and architect, and in aid of any charity for such a purpose, and this annuity in perpetuity." By the details stated in the will, it would appear the amount of the dividends applicable to this purpose is 10*l.* per annum. The executors appointed in the will were Mr. William Baxter of Clapton, and Mr. George Booth of Bucklersbury.

Doubtless this trust property has hitherto been honourably appropriated; still, as there are no doubt many now living who would be grateful for such aid, and whose cases come within the limited description, it would afford them some satisfaction to know that prior claims alone prevented their participating in the benefit, and I trust such information may be granted them through the medium of this journal. Perhaps also it might be well for the Institute of British Architects to keep a note of the circumstance in their records, for reference on some future occasion of a vacancy: and I trust this bequest may be the nucleus of a much more important provision for those who, in a greater or less degree, may be helpless and destitute.

I am, Sir,

Your very obedient servant,
A CONSTANT READER & SUBSCRIBER.

July 11, 1842.

P.S. Allow me to suggest to any of your readers who may possess information of any other similar bequest, that they would be conferring a great benefit by giving it publicity.

REVIEWS.

IRON SHIP-BUILDING.

1. *Iron as a Material for Ship-building.* By JOHN GRANTHAM, C. E. London: Simpkin and Marshall, 1842.
2. *Paper on the same subject, read before the Liverpool Polytechnic Society,* given at page 124 of this volume.

It is rather surprising that it should have been reserved until the present day to apply iron extensively as a material for ship-building. We have been so long acquainted with the capability of metals for floatation, we have availed ourselves of this property so frequently, both in ordinary pursuits, and for many important purposes, that the non-application of it to ship-building appears almost unaccountable. Military men, we should have thought, would long since have had their attention drawn to it, being familiar with the metal pontoon in the erection of temporary bridges. It is from the beginning of this century, however, that we must date our history of the subject, when we find iron boats employed on some of the canals, particularly in Staffordshire. Mr. Grantham's firm seems to have engaged in the construction of these boats as early as thirty years ago. In 1815, a Mr. Jevons, of Liverpool, launched a small iron pleasure boat on the Mersey, which completely answered his expectations. It seems to have been maliciously sunk in the Duke's Dock, where it was subsequently found when the dock was emptied for repairs. In 1817, Mr. Jevons made arrangements with Mr. Horton for establishing a yard at Liverpool for iron ship and boat-building, and in 1818, lodged a caveat in the Patent Office with the view of taking out a patent for an iron life-boat, the model of which was exhibited in the underwriter's room at Liverpool. The death of Mr. Horton frustrated these plans. The iron life-boat appears to have met with the fate of its predecessor, having, after a disappearance for some time, been found in the Mersey with holes drilled in her chambers; she was, however, repaired and sent to the West Indies. In 1820, Mr. Aaron Manby took out a patent for iron steam-boats in France, a measure which appears to have given the first impetus to this branch of metallic industry. A vessel called the *Aaron Manby* was built by the Horsley Company for the Seine, and in 1822, started from London for Havre. She was commanded by the present Sir Charles Napier, K.C.B., who co-operated with Mr. Manby in the enterprise, and from Havre was navigated to Paris, having been perhaps the first and only vessel of any description which ever went direct between the two capitals. Mr. Manby afterwards established ironworks at Charenton near Paris, and built other iron boats, which boats continue in work up to the present time. The next step we have to notice was the construction of an iron steamer for the Shannon, under the direction of the elder Mr. Grantham. Mr. John Laird of Birkenhead afterwards commenced building iron vessels on a large scale, as did Messrs. Fairbairn and Co., and Ditchburn and Mair of London. At a subsequent period Mr. Fairbairn of Manchester undertook a series of experiments at Glasgow in which iron vessels were employed. Subsequently Professor Airy, the Astronomer Royal, undertook the task of ascertaining a mode of correcting the magnetic compass in iron vessels, and providing against the effects of local attraction. Captain Johnston also investigated this subject on the Shannon, and Mr. Grantham at Liverpool. Mr. Holmes, in his pamphlet on steam navigation with the Indies, seems to have been one of the first to advocate the system of iron steamers on a large scale, and although he wrote so late as in

1838, his views then seemed in advance of the day; subsequent experience, however, has gone far to prove their correctness. Two years ago Mr. Creuze, of Portsmouth Dockyard, took up the subject, and was one of the first to treat it practically. We may mention incidentally that the late Mr. Egerton Smith, of Liverpool, took a share at an early period in the advocacy of this, as of so many improvements. Mr. Grantham read a paper on the subject of iron ship-building before the Polytechnic Society of Liverpool, of which he is the President, and this paper has swollen into a goodly treatise now lying before us, and to which we are indebted for the materials on which our present remarks are based. Thus dismissing the literature of the subject, we shall resume its history by reminding our readers of the great progress made of late years. The Government has begun an iron steam navy, the powers of which have been tested and established on the coasts of Syria and China. The East India Company have followed the same example. To the East and West Indies and to South America, iron sailing vessels of a large size have been sent, and have overcome the difficulties and prejudices which were opposed to them. One of the largest of this class is the *John Garron*, of 711 tons, and we cannot refrain from saying that the owners, Messrs. Anderson, Garrow, and Co., are deserving of a high meed of praise for having steadily and perseveringly prosecuted their exertions under most discouraging circumstances. The *John Garron*, from bad construction, turned out a heavy sailer, and it became necessary to lengthen her and remodel her lines. The bold attempt of Mr. Brunel in the plan of the *Great Britain* steamer, is one of those events which have fixed public attention, and the issue of which is anxiously regarded. For sea and river navigation, and for towing, the iron steam-boat has shewn very great capabilities, and has established itself on the Thames, the Shannon, the Mersey and the Clyde, on the Seine and the Elbe, on the Nile and the Ganges.

To appreciate the causes which of late years impeded the extension of iron ship-building, we must consider the serious prejudices arrayed against it. It was represented, that however serviceable the iron boat might be on the river, that on the ocean it perilled the life of the mariner, and the property of the owner. It was said that the disturbance of the compass by the mass of the vessel was irremediable, and that the seaman was thus deprived of his greatest safeguard. Beyond this a disposition to drift to leeward, and unsteadiness under the helm, were charges scarcely less formidable. It was said, too, that the speed of the vessel would be impeded by fouling, as the metal surface of the hull became covered with barnacles and weeds. Nay, the vessel itself was held forth as perilous, as liable to corrosion from the sea-water, and consequent destruction of its substance. The stiffness of the hull is another imputed defect, tending to the diminution of the sailing power of the vessel. These serious charges produced their due effect; from whatever cause emanating, whether from the interested suggestions of timber ship-builders, or the spontaneous effusion of timid ignorance, the seaman was alarmed, the ship-owner deterred, and the underwriter raised the premium of insurance. Thus an accumulation of difficulties was created, which the energy, enterprise, and public spirit of those engaged has alone been able to remove, however groundless the charges have turned out to be. The phenomena of magnetism, as connected with iron vessels, are but little known, but it has been established by the experiments of Captain Johnson that an iron-ship becomes a large permanent magnet, having a strong magnetic current in the direction of the ship's length, and causing a serious disturbance to the general polar direction towards which the needle points, and to which it must be made again to turn itself. This Professor Airy has successfully effected, and many long voyages have been made in iron vessels with compasses so corrected. The carelessness of captains of ships has occasionally thwarted this measure, but its soundness has not been impugned. Professor Airy mentions a singular instance with regard to this question. The compasses in an iron ship had been corrected by one of the Messrs. Simms, the mathematical instrument makers, and the ship left the docks in the Thames for Gravesend; at this latter place the Captain stopped and rode up to London in a state of frenzy, having found the action of his compasses most erroneous. The person who had corrected the compass instantly went to Gravesend, and there to his astonishment found that between the time of having corrected the compass and that of the sailing of the vessel, a large iron stove had been erected near the binnacle. Professor Airy truly observes:—"This vessel might have been lost on the shoals of the Thames on her first voyage, and not a word would have been heard about the iron stove." In treating of the magnetic action in the compass, Mr. Grantham takes the opportunity of mentioning that an iron vessel is formed of an immense number of plates and bars of different forms, having varying degrees of magnetic force, and the electric currents running in various directions. As a curious question arises as to the period at which the current

begins to take a uniform force through the vessel, and neutralising or turning into one channel the multitude of conflicting currents, Mr. Grantham has undertaken to make experiments on the subject. It has been supposed that the course of the magnetic current is determined during the operation of rivetting, or that its intensity is considerably increased, its force being also influenced by the polar direction of the ship's keel while on the stocks, but Mr. Grantham states that he has been led to doubt this. The polarity of the ship, he considers, is not affected by rivetting, but seems to be dependent on the quantity or quality of the iron, and he thence deduces that there is reason to believe that time will have but little effect in increasing or diminishing the magnetic intensity. Captain Johnson, we may add, has observed, that the compass placed a few feet above the deck is not much attracted by the iron, and it is a common practice for the captains of iron ships to place a compass in the cross-trees at the top mast-head, by which to ascertain the correctness of the one placed in the binnacle. Sir Howard Douglas has raised the question whether the changes of climate are likely to affect the intensity of the electric current. We think they might in a slight degree, but experience has proved not to such an extent as to interfere with the safe action of the compass. The long voyages to the East and West Indies, and to South America, have abundantly proved the efficiency of the compass in iron vessels. As to iron vessels being more subject to drift to leeward, and steering ill, as these are circumstances dependent on form, they can be no peculiar defects of iron shipping. The navigable powers of iron vessels, when properly constructed, are as perfect as those of timber vessels; but it is the case that many iron ships being built for a light draught of water, are flat-floored, and very full, without adequate and counteracting depth of keel. This, however, has nothing to do with a deep-sea ship. Fouling in the case of iron ships has been much exaggerated, for it can be entirely got rid of by the application of a scraper, such as Mr. Grantham has invented and described. The corrosion of the iron plates by the action of sea-water proves a groundless alarm—no case of destruction from this cause in many years' experience has yet occurred. Mr. Grantham remarks, that so slight is the apparent decay of the vessel when in use, and so much slower in its progress than is exhibited by iron when applied to other purposes in salt water, that many who have observed the fact, are led to suppose that some occult and preservative law is in operation peculiar to iron so employed. The phenomena of iron rails on a railway will occur to our readers on this occasion, and also those affecting wood pavement. As oxidation is promoted by heat, Mr. Grantham recommends that in steam-boats the boiler should be kept as far as possible from those parts of the vessel which are above water, or means should be adopted to keep them cool by interposing non-conducting substances. The connection of copper pipes with the shell is also to be avoided, and for this purpose the same gentleman states that he has latterly made short lengths of wrought iron pipes, with flanges, and rivetted them to the vessel.* It was assumed that iron vessels would be found unsuitable for warm climates, as subjecting the crew to a greater heat, but neither in the Niger, or the Euphrates, nor in the China Seas, has this proved to be the result. Even at home ship-owners have been deterred from the use of iron by the fear that the public were prejudiced against it, although the experience of the Glasgow and Liverpool steamers, and other large vessels, shows no such unwillingness. We agree with the author before us in regarding stiffness of hull as an advantage and not an injury to the sailing power of a vessel, provided the elasticity of the rigging is sufficiently secured. The prejudice of the underwriters with regard to iron vessels, will most likely turn out very much in the same way as that with regard to chain cables. They would not formerly insure a vessel which had chain cables; then it came to the use of one cable of hemp and another of iron, and now most probably underwriters would object to a ship as insufficiently found if she had no chain cable on board. If the underwriters do not give way with regard to iron ships, the owners and builders have the remedy in their own hands, for it is in contemplation on their part to form a marine insurance company of their own.

Having now disposed of the objections to iron shipping, we shall refer to some of its merits. The first cost is perhaps the feature of primary interest: on this subject Mr. Grantham sums up.

"From a careful consideration of the question of cost, I have arrived at the following conclusions:—

"1st. That a good serviceable iron sailing vessel, not exceeding 300 tons burthen, will be equal in cost to an English-built twelve years timber-built ship, of the same external dimensions, without including the price of copper sheathing for the latter.

* On the subject of corrosion of iron, and the means of remedying it, see Mr. Mallett's Papers in this Journal, vol. i, p. 312; and vol. iii, p. 387; Mr. Neilson's Patent, vol. iii, p. 363; and Mr. Wall's, vol. iii, p. 429.

"2nd. That iron vessels of above 300 tons have the advantage of being rather less expensive than wooden vessels.

"3rd. That for very large merchant vessels and ships of war, iron will also be found to be much less expensive than wood.

"4th. That iron sea-going steamers bear also about the same proportion according to their different sizes.

"5th. That iron vessels, for rivers, may be built at a light expense, but so built are unfit for sea service."

The prime cost, presenting this immediate advantage, is not the only pecuniary benefit; for iron shipping, from the durability of the material, requires few repairs, and when broken up is more productive than timber. Repairs, the great source of profit to other ship-builders, can never accrue to the iron ship-builder to an equal extent. The hulls of some of the large Clyde steamers have not cost 1*l.* these five years, while the usual calculation for a timber-built steamer is that the expense of repairs will in ten or twelve years have equalled the first cost. The advantage, in case of breaking up, is in favour of iron as against timber, four to one. Turning to their physical merits, we should premise that malleable iron is one of the strongest materials,* while it may be converted into any shape; on the other hand, timber for curved parts must be grown with great trouble in an unnatural form, or else scarfed, and its strength consequently impaired. The ease, moreover, with which iron beams and frames of any dimensions and in one piece can be wrought, overcomes one of the greatest difficulties in ship-building. As regards the mode of fastening, copper and iron bolts must be used to secure the frames of a timber-built ship, and are so badly contrived that they have little hold, while they are the source of destruction to the ship, as being of a different substance. Mr. Creuze sums up well on this point. He says of iron,

"Among the advantages are the greater durability of the material, not only from its relative durability with that of timber, but from its requiring no such metallic sheathing to protect it from the ravages of worms. Also the greater durability of the structure, as a whole, in consequence of the greater permanency in the perfect combination of its several parts, arising from the fastenings being of the same texture as the portions of materials brought into connexion. The metallic fastenings to a timber-built vessel act, it must be remembered, not only chemically, but also mechanically, to accelerate her destruction so soon as the close connexion of the several parts is at all diminished."

A wood vessel is compared by Mr. Grantham to an arch, being made up of a great number of parts of various forms and sizes, placed in different directions, and being dependent on each other for support. If one becomes loose, the whole structure is more or less endangered. In consequence, a most elaborate system of bracing by iron straps, knees, and bolts with nuts, is now pursued. The bolts do not accord with the materials they fasten together, and the wood is so soft that when a severe strain arises, a general yielding takes place, by the boltheads sinking into it, and the wood itself giving way to the pressure it receives from the neighbouring parts. In the iron vessel, on the other hand, the outer shell of the vessel is composed of a series of plates so rivetted together that its strength is nearly equal to that it would be if formed of one plate. The consequent strength of iron vessels needs little to be said in proof. On the canals the iron boats are put to the severest service, as carrying iron stone, pig iron, and refined iron from the blast furnaces. Mr. Grantham refers to many instances of vessels getting aground and on rocks without injury, and several cases of their being left resting on one or two points of support, without any strain to the framing. A large casting, weighing four tons, is mentioned as having fallen into the hold of the Princess Royal, Glasgow iron steamer, in consequence of the tackle having given way, but without damage to the vessel. Greater capacity for stowage is one of the grand points on which iron shipping claims superiority. Mr. Grantham treats it thus:—

"The shell of a timber-built vessel is so much thicker than that of an iron vessel, that, with the same outside dimensions, the latter is frequently 18 inches wider and 12 inches deeper in the hold than the former. Taking the most favourable part of a vessel—namely, in the centre of the length—in a vessel of 200 tons, the proportion in favour of the iron vessel will be as 5 to 6; but in the ends, which are drawn finely off, the disparity is much increased, making the proportion of the whole contents about as 5 to 4. Supposing, therefore, that a vessel built of timber could stow 200 tons, she would, if made of iron, have room for 250 tons. The total capacities of the largest vessels will probably not approximate nearer than as 5 to 6; making the iron ship of 600 tons not to exceed in outward dimensions the timber one of 500 tons. The advantage of this is very great, and enables an iron

* Vide Mr. Fairbairn on the Strength of Iron, with respect to Ship-building, in our third Vol., p. 388.

vessel to trade, and remunerate the owners, in cases in which a wooden vessel would not return a profit; for, if we suppose that the freight of a 500-ton ship would just pay the expenses required to navigate her, an iron vessel would leave the freight on the extra 100 tons as clear profit."

"An iron vessel required to carry 250 tons, therefore, equals, in the first cost, a wooden vessel that will carry only 200 tons; and an iron vessel required to carry 600 tons will cost less than a wooden vessel built to carry only 500 tons."

Again, of steamers he says,

"The comparison is much more in favour of iron than with wooden vessels. As the average cargo of a steamer is only, perhaps, about one-third of the load, in engine, cargo and coals together, an increase of one-fourth in her stowage adds 75 per cent. to her capacity for carrying cargo. In other words, to carry a given cargo, the iron steamer may be much less than a wooden one."

Light draught gives the iron ship the monopoly of shallow rivers, and cannot fail to lead to a great extension of navigation. The Indus, chiefly on account of physical difficulties, has hitherto been a closed river; the employment of the new class of vessels must, therefore, create a large traffic on its waters. Cleanliness is a mercantile quality, and is accompanied by health, the nuisances of bilge water and vermin being got rid of in the iron ships. With regard to the latter annoyance, it is related that a colony of rats took possession of the *Iron Duke* previous to her first voyage, but not relishing the obdurate material of which she was built, a portion of them deserted her at Calcutta, and the remainder immediately on her return to England.

Strength goes a great way to ensure safety in a vessel, and iron plates in strength are, to English oak, as 49·68 to 10·01, or nearly 5 to 1. Iron ships are further to be preferred in this respect as readily admitting the division of the hull by bulkheads. Superior speed Mr. Grantham claims as one of the results to be expected from the extended use of iron. He considers that the cheapness and flexibility of this material will allow of the model of a vessel being made finer, without corresponding loss in the amount of steerage, and in the carrying qualities. In the event of accident, the repairs of iron ships are very trifling, as instanced in the case of the *Nemesis* war steamer, which ran on one of the Scilly rocks in the British Channel with such violence that, to use the expression of Captain Claxton, "if she had been of wood she would most probably have left her bones on the spot." She was, however, navigated round to Plymouth, and the repairs easily effected for about 30%. On the subject of repairs the author so often quoted declares that it is erroneous to assume that iron vessels are more difficult to repair than those of timber, for the injuries are generally external and confined to a single spot, and may in most cases be sufficiently repaired by any ingenious man, if the ship be but provided with a few drills, spare plates, bolts, and other necessary articles, which no captain should neglect to carry among his stores. Besides, he says, when iron vessels become more generally employed, the necessary assistance will be found at all considerable ports and stations at which they may touch. We may add, too, that ultimately the ship's blacksmith will be rated instead of the ship's carpenter, or perhaps in Queen's ships the rating of the armourer raised. In warfare the resistance of the iron sheeting to the impact of shot striking the hull in an oblique direction is an advantage, while even a shot entering the vessel is less injurious than in timber ships, as no splinters are produced—the great cause of death and wounds. Shot holes in iron sheeting admit of being readily stopped, and in an easy manner. The injury from the recoil of heavy artillery, such as is now used, is less on board an iron ship, and enables them to carry a heavier armament.

It is to be regretted that, in their anxiety to secure contracts, iron ship-builders have sometimes been tempted to construct vessels of a less degree of strength than due consideration would have dictated, and have thus endangered the success of the system. Plates of all forms and dimensions have hitherto been used, from $\frac{3}{4}$ to $\frac{3}{2}$ of an inch in thickness, but Mr. Grantham observes that these are by no means the limits within which the plates must of necessity be made; some of much greater strength will, in the farther progress of the art, most probably be put in requisition. Of late, as the size of the vessels has increased, and the extent of the voyages performed by them, the strength of the plates has been increased. On strength of material it is to be remarked, that oxidation proceeds no faster on the surface of thick plates than of thin plates; so that plates of $\frac{1}{2}$ inch have double the durability of those only $\frac{1}{4}$ inch in thickness. In his remarks on jointing Mr. Grantham decides in favour of the lapped joint in preference to the flush joint, and also in favour of double rivetting. By Mr. Fairbairn's tables read before the British Association at Glasgow, it appears that, assuming the strength of plates to resist tension

to be 100

A double rivetted joint will be 70

And a single rivetted joint 56

In the system of flush-jointing, twice the number of rivets are required; and, therefore, to obtain the advantage of double rivetting, four rows of rivets are necessary to each joint.* As to the objection which has been raised to the lapped joints, that they make the hull rough and lessen the sailing powers, Mr. Grantham's defence is that it is very questionable whether the edges, presented in almost straight and parallel lines, can at all impede the vessel's velocity, while they give her a better hold of the water. In reference to an inquiry whether, in case the heads fly off and the rivets fall out, the strength of the vessel is lessened, and a hole left for the admission of water, our author observes that he never heard of such an accident, and that in his yard no occasion has been found to replace a single rivet. Should, however, the head of a rivet break off while the vessel is afloat, it by no means follows that the rivet itself should fall out; on the contrary, when originally secured in a workmanlike manner, the piece remains so firm in the hole as to require the application of a strong sledge to drive it out. Among the errors to be guarded against, Mr. Grantham places that of bolting on a false keel of timber to an iron vessel, by which the *Iron Duke*, a vessel of 350 tons was nearly lost, for having struck heavily on a sandbank, she tore away the false keel, and broke off the bolts by which it was fastened, so that the water entered the holes.

Considered as a national question, and with regard to its capability of extended application, the use of iron in ship-building acquires a great importance. At present the shell merely is of iron, but the decks and bulwarks must ultimately be made of that material. In the shape of chain, iron has been extensively used for cables and for running rigging, for halliards, topsail sheets, &c., in which latter capacity it is found to be superior to hempen cordage as being much more slender than ropes of the same strength, so that it will pass through smaller sheaves or blocks, while it stands better to its work from not being subject in atmospheric changes to any perceptible expansion or contraction. The introduction of wire rope will, under such circumstances, evidently lead to a greater use of iron even for rigging. For masts, iron has also been adopted, and Mr. Grantham mentions one as in use for upwards of twelve years in the *Ballinasloe* steamer, without sustaining any perceptible loss in its strength. This mast serves also as a ventilator to the cabin. As we stand now with regard to materials for ship-building and rigging, we are dependent on foreign countries, while our builders labour under great disadvantages in competition with their foreign rivals with regard to both timber and hemp, the raw materials of their art. Little timber, be it remembered, is grown in this country, where it is a precarious and little profitable production, subject to the ravages of the worm and of fire, and requiring many years before it brings a return. Neither does it give much employment to labour in its production or subsequent application. Mr. Grantham, on this subject, remarks in a paper read before the late meeting of the British Association at Manchester, that the *Hindostan* timber vessel had cost £72,000, of which about £12,000 was for labour, and £48,000 for wood, and much of this was expended in the East Indies; but an iron ship of £72,000 value would cost £67,000 in labour, all expended in this country, and the remaining £5,000 would also be paid here for the raw material. Were iron substituted for timber and hemp, we should not only give greater employment to labour in our mines, but also in our building yards and to our seamen, for now the inducement is to build ships in those countries where the material is most abundant, while we cannot compete in freight with ships built by several other nations, owing principally to the comparatively low rate at which they can procure the materials for building.

The steam navigation interest is that which has the most to look forward to from the general introduction of iron. At the present day, the machinery and fuel occupy so large a portion of the vessel, that very little room is left for stowage. The weight and tremour of the engines shake and strain wooden vessels and the machinery itself, until the repairs of both swallow up most of the profit which would otherwise be realized. The necessity for a greater degree of adaptation between the vessel and the machinery, is a topic which Mr. Grantham has well handled. The engineer, he complains, is generally very regardless of the requirements of the vessel, and the ship-builder often clings to principles of construction, which, when applied to steamers, are ill suited to the attainment of a high speed. A wooden vessel, when she takes the ground, and frequently when she encounters heavy weather, becomes so much altered in shape that, were the engines so attached as to form part and parcel of the whole, they would

* Vide also Mr. Fairbairn on rivetting boiler plates by machinery, at page 351 of our 3rd Vol.

be in danger of being broken down, or otherwise injured. Few timber steamers, he adds, can be placed in the graving dock, without first slackening the holding-down bolts of the engines to allow the vessel to spread out, lest the framing should be broken. Were iron vessels general, the case would be different; the engineer might, with perfect safety, firmly unite the vessel and the engine, being the designer of both; and being responsible for the success of the whole, he will not allow one part to suffer for the benefit of the other, but labour to combine both so that they shall mutually support each other. "Then, indeed," says Mr. Grantham, "we may expect to see a perfect steamer."

In conclusion, we feel it our duty to say that the public are greatly indebted to Mr. Grantham for having taken up this subject, and treated it with so much ability.

The Theory and Practice of Propelling through Water, with observations on the Comparative Resistance offered by Water to Bodies moving through it at different Velocities, comprising also a Description of an Improved Method of applying Mechanical Power to Steam Navigation. By HENRY BOOTH. London: John Weale.

MR. BOOTH is so favourably known to practical men by his past successful exertions in the cause of steam improvement, that any speculations of his, relative to such subjects deserve an attentive consideration, and are almost sure to obtain it. The ultimate object of his present pamphlet appears to be the recommendation of a plan of propelling vessels he has invented, and from which he anticipates far greater efficacy than can be obtained by any modes at present in use; and he seems to found this anticipation partly upon the conviction that the received theory of resistance is erroneous, and he calls upon engineers "not quietly to acquiesce in the appalling theory which ordains that 30 horse power being required to move a given vessel and burthen 5 miles in the hour, 240 horse power will be required to move the same vessel and burthen 10 miles in the hour." Mr. Booth's conviction of the inaccuracy of the received theory of resistance is founded upon the results of certain experiments which he relates, and which, if correctly conducted, certainly present some anomalies not very easily explicable. In experiments with models for ascertaining their resistance when moving in water, he objects to the use of a weight moving at very different velocities as the true representative of the amount of power expended. He says, and his assertion is obviously true, that a weight which descends 10 feet in 3 seconds does not give out as much power as the same weight falling the same distance in 6 seconds, and that at the velocity due to the descent of a body falling freely, no power could possibly be given out; and he supposes that the apparently great increase of resistance to models moving in water at high velocities, is partly due to the diminished efficacy of the weight as a moving power, the velocity of the weight's descent having in many experiments at least been increased with the increased velocity of the model. By making such arrangements in his apparatus that the time occupied by the weight in descending through a given space was always the same, and the velocity of the model varied by the use of larger or smaller drums for coiling up the string, Mr. Booth has obtained results very different from those obtained where the drums remained of the same diameter, and the increase of the velocity of the model was attended by an increased rapidity in the descent of the weight.

There are several circumstances which prevent the results of the experiments from being conclusive in our eyes. The different degrees of the immersion of the models do not appear to have been noted; and the want of uniformity in this respect is an obvious source of fallacy. At high velocities it is well known models and light boats will rise almost out of the water, and their resistance will then be very little; and whether this source of diminution in the resistance may not have existed in these experiments—or to what extent—we are unable from the details before us to assert. Mr. Booth will probably tell us, that the velocities in the cases from which he has drawn his results were equal, and that therefore the effect proper to the diminished immersion of the boat must be equal also. But he must recollect that the boat in the one case travelled a greater distance than in the other, and although it is true that 7 ft. 6 in. of progress in 3 seconds is equivalent to 15 ft. in 6 seconds, yet the rates of progression are different, and the sum of the resistances may consequently be unequal. In other words, if 15 feet be travelled over in 6 seconds, less than half of the 15 feet will be accomplished in the first 3 seconds, and more than half in the last 3 seconds, the velocity being accelerated; and in the cases where the 15 feet were passed over, there may

be a diminished resistance in the first part of the motion from its greater slowness, and in the last part of the motion from the diminished immersion of the model.

There are other sources of fallacy to which we cannot now advert, and must content ourselves with saying that we do not think any experiments upon the resistance of bodies moving in water, where the prime mover is a weight susceptible of acceleration in its descent, are in any degree entitled to confidence. Major Beaufoy employed a chain, the links of which were raised successively from the ground by the descending weight, to counteract the tendency to acceleration. Other experimentalists have made use of governors, and other contrivances for the same purpose, and the resistance has been measured by a dynamometer. All the experiments so conducted have been confirmatory of the received theory; and we shall be willing to put equal faith in Mr. Booth's researches so soon as he shall have adopted similarly efficacious means of obviating error, and holds the immersion of his models at the different velocities to be a necessary element of the inquiry.

But it is not upon experiment alone that the received theory rests its pretensions; running water and wind, it is well known, impinge upon stationary objects with a force increasing as the square of the velocity, and the atmospheric resistance to railway trains follows the same law. If water be let into an inclined shoot, the velocity of the water two feet down will be twice what it is at one foot down; and as it is the same quantity of water which runs at twice the velocity, the depth of water in the shoot at the lower level will be only one half of what it is at the upper. Now every particle of water which falls two feet will, by virtue of the fundamental laws of mechanics, have just twice the force as every one of those which have descended one foot; and a particle of water will therefore strike any object at the lower level with just twice the force that it would do at the upper; and all the particles of water in the shoot, if striking against a body, will just give out twice the force at the lower level that they would do at the upper. But at the lower level they occupy only half the depth in the shoot, and therefore impinge upon only half the area; and a doubled force upon half the area is just a quadrupled force upon the whole area, which is the received theory. Mr. Booth says a considerable part of the resistance of ships is made up of friction, and that friction does not vary as the square of the velocity. To this it is only necessary to say that we know so little about friction, that we hold it unwise to draw any analogies from it. Friction, we know, is increased by increasing the rubbing surface, and increased also by diminishing it; it is increased by allowing two pieces of some substances in contact to remain for a few minutes at rest, whilst in other cases no apparent increase takes place, and it is certainly affected by many causes which we cannot hold to be mechanical. Besides, we do not believe that friction forms any considerable part of the opposition experienced by a vessel in moving through the water. The speed of a steam vessel is always increased, at least in smooth water, by increasing her length, and in some cases, as Mr. Booth, in another place asserts, by increasing the breadth; but in both of these cases the friction is increased. Thus much we have found it necessary to say in support of the received theory of the resistance being as the square of the velocity; but whether as the square of the velocity or as any thing else, we do not think it to be at all relevant to the merits of Mr. Booth's propellers. Whatever the resistance may be, it is unchangeably fixed in the nature of things, and has to be overcome by Mr. Booth's propellers, just as much as by any others. Propellers may vary in expending the engine power more or less beneficially, but they cannot alter the resistance of the ship, and we are at a loss to discover the reason of these two questions having been mingled together in Mr. Booth's pamphlet.

The system of propulsion Mr. Booth recommends, may be understood by supposing a double arm upon each side of the ship, extending from the ordinary position of the paddle centre to several feet before the water level, moved backwards and forwards by the engine, and furnished with a plate moveable upon an axis at its lower extremity. This arm consists of an inner and outer portion, between which the plate is situated, and this plate is so hung that upon the advance of the arm the edge is presented to the water, and upon the retrocession of the arm the flat surface of the plate is presented. The plate thus opens and shuts in the frame containing it, something after the fashion of a throttle valve, and there are springs upon each side, to prevent it from opening or shutting with an injurious force. Mr. Booth also intends that his project shall be in active operation during only a small portion of the stroke of the engine, the power given out by the engine during the remaining portion being accumulated by means of fly wheels, to give a speed to the propellers during this short interval of 3½ miles per hour. The action proper to a row-boat is thus approximated to, and horses are imitated, who, in pulling a boat, always

exhibit the principle of concentration. "Thus nature works, and we only endeavour to imitate Nature in her most successful efforts, by the alternate concentrated operation of the patent propellers."

We confess it appears to us there is much want of judgment and much puerile jargon in all this. If the propeller be moved at 31 miles per hour and the vessel at only 10, every stroke of the propeller will put in motion a column of water of an area equal to the propeller, with a velocity of $31 - 10 = 21$ miles per hour; and as this water is moved by the engine, a great part of the engine power is thus uselessly expended. Mr. Booth is probably not aware that by increasing the velocity of the paddle-wheel by reducing the area of the float, and thereby increasing the consumption of steam by the engines, and consequently the power, the velocity of the ship is actually diminished in some cases. Twenty strokes of the engine per minute will thus sometimes be less effectual than 15, though with the same pressure in the cylinder in both cases; and the cause is, the difference between the speed of the paddle and the speed of the ship is then too great, and much of the power of the engine is expended in throwing the water back, instead of forcing the vessel forwards. As to the imitation of the expedients of Nature, we must beg leave to insinuate that Nature is best copied when the means devised are the most answerable to the purposes for which they are intended; and that to copy ducks' feet and horses' legs in works of art, merely because Nature employs such agencies, is to depart from the principle by which Nature operates, in the exact proportion of the fidelity of the imitation.

We are unable to extend our remarks further, and there are many heresies which must, therefore, remain unnoticed. We regret that we have been compelled to be so uniformly censorious, but Mr. Booth can well spare the reputation which the best of such schemes is able to confer, and neither is nor needs to be a mendicant of praise. He will, therefore, we are sure, pardon us for stating our honest conviction, that this is one of the very worst plans of propulsion that has ever solicited the favour of the public.

Transactions of the Royal Institute of British Architects. Vol. I. Part 2. London: Longman and Co., 1842.

"BETTER late than never." After a gestation of six years (for Part I. of this work bears the date of 1836), and a parturition of we know not how many months since it was advertised as preparing for the press, the representatives of the architects of Great Britain have at length brought forth what they facetiously call *their Transactions*: theirs, it must be presumed, upon some principle of appropriation, since, out of the one hundred and eighty-five pages of which the volume (or half volume) consists, less than thirty are the production of the professional members of the Association by whom it is published. And of this small contingent, by far the greater portion belongs to the late and present honorary secretaries, upon whom it was perhaps incumbent to contribute something *ex officio*—so at least it might be supposed, judging from the easy tooth-pick sort of way, in which one of these gentleman dispatches a subject upon which he might have told us a great deal if he had pleased, and *per contra*, the laborious illustration of an Arnott's stove! undertaken by the other. There remain, therefore, only some half dozen pages, devoted to an investigation of that remarkable arch popularly called the stone beam, in Lincoln Cathedral, which it is possible to consider as a free will offering from any member of the profession, towards promoting the objects which the Institute may have in view in the publication of their proceedings, and for this we are indebted to Mr. Nicholson of Lincoln. It is very certain, as every one knows who knows anything of the proceedings of literary and scientific societies, that a paper may be most interesting and valuable as addressed to a general meeting and accompanied by illustrations, and yet possess neither importance nor novelty to entitle it to permanent record; and yet it seems strange that an interval of six years, during which something supposed to be worth listening to has been read at every meeting of the Institute, should have produced so little which on review should appear worth preserving. It is impossible but that the eminent architects who appear among the members of the Institute, should meet with incidents in the course of their extensive occupations which might suggest valuable communications on practical subjects; but the fact is, that we find the names of none of those professional gentlemen whose means of observation are the most enlarged, either in the body of this volume, or in the list appended to it of nineteen papers read at the ordinary meetings during the session of 1840-41, of which nineteen papers, be it further remarked, eight only, exclusive of two translations, are claimed by the professional members of the Institute.

We say all this in no unkind feeling towards our professional friends. We admire sincerely the spirited endeavours of the Institute to carry out some of the most important objects for which the members professed to embody themselves, and if they have not been supported by all who are interested in their proceedings and who profit by them, the fault is most assuredly not theirs; but if the Institute seek to be recognized by the public as a literary society, they must exhibit a little more energy in the performance of the character they assume. The profession in general may not be such ready writers as some others, yet there are those among them who are sufficiently familiar with the printer's devil; and unless some of them will show a disposition to contribute at least a reasonable quota to their own publication, they can scarcely expect the continuance of that aid from their honorary members, and others not bound to the Institute even by that slender tie by which alone they have been enabled to produce the volume before us. If these gentlemen hold the honour of appearing in the *Transactions* of the Institute at a discount, we disagree with them. They may go far without finding themselves in better company.

These observations must be understood as totally independent of our opinion of the volume itself, which is one of the most valuable offered to the profession and the public for a long time past. It consists of ten papers or essays, illustrated by numerous engravings and wood-cuts. The first in order is a dissertation "On the mechanical construction of the Vaults of the Middle Ages," and the name of Professor Willis is a sufficient guarantee that it has been treated in the most able manner. The subject of stone vaulting in general is one which has been hitherto much neglected by English writers, and the works of foreigners, beginning with the celebrated treatise of Philibert de l'Orme, published in 1568, have been entirely devoted to the forms of vaulting peculiar to the classical and Italian styles of architecture, and they have exhausted their ingenuity in devising methods to meet all cases of obtaining, from plans and designs, the forms of the individual stones of a building for the use of the mason, and these operations have always formed a regular branch of architectural science in France, under the name of the "*coupe des pierres*." The necessity of regular laws and systems to the Gothic architects in the construction of their marvellous vaultings is obvious, and much of their practice is probably mixed up with the problems of De l'Orme, who treats his subject as one well known, and claims only the merit of first reducing it to writing; but of their peculiar methods nothing has been transmitted to us.

"It becomes, therefore," says Professor Willis in his introductory pages, "a curious and interesting subject of inquiry to trace, from an examination of the structures themselves, what geometrical methods were really employed in setting out the work, and how the necessity for these methods gradually arose. Independently of the value of such investigations to the history of the science of construction, the knowledge of the methods actually employed would greatly assist us in the imitation of the works of each period. For the forms and proportions of every structure are so entirely dependent upon its construction and derived from it, that unless we thoroughly understand these constructions, and the methods and resources which governed and limited them, we shall never succeed in obtaining the master key to their principles, and instead of *designing* works in the style of any required age, we must content ourselves with merely *copying* them."

"The following paper must be considered as an attempt to sketch out an investigation of this kind, and in offering it to the body of practical men who are assembled in this Institute, I am not without hope that some of them may be induced to collect facts and examples by which this investigation may be carried on and completed. For it will appear, as we proceed, that most of the facts required are of such a nature that they can only be derived from the existing buildings by the aid of scaffolding, minute measurement, and close observation, which it is not often in the power of mere travelling observers to obtain."

"Now professional men are so commonly entrusted with the repairs or restoration of these old structures, that if they would take the opportunity of making the required observations in every case where scaffolds were erected about a building, and if such observations were transmitted to the Institute, a few years would suffice to bring together a body of examples from which general rules might be deduced. It is only by comparing many examples that this can be done, for general rules deduced from single instances are commonly worthless."

The subject thus proposed the author follows out in four sections, devoted to the consideration of—the general construction of the vaults of the middle ages; the curvature of the ribs; the ridge ribs, liernes (or short ribs in decorative vaulting), and bosses; and lastly fan vaulting, upon which so much ignorance has been promulgated, and so much learning expended, both of which are dispelled before Mr. Willis's simple and clear-headed investigation of facts.

The first section begins by pointing out the essential difference between Roman and Gothic vaulting, the latter consisting of a framework of ribs or stone arches, upon which the real vaulting is supported, a mode of construction which the author designates as "rib and pane work." In the early stages of vaulting, during the Norman period, these ribs offered very little geometrical difficulty, but as the number of ribs was increased, a more artificial mode of structure became requisite, and the investigation of the mechanical processes by which the arch stones might be fitted to each other, so as to produce the existing results, occupies the remainder of section 1. Among the diagrams which illustrate this portion of the work are exhibited the working lines left by the masons on the beds of the voussoirs of ancient arches which have been taken down. In section 2, the first point considered is the difficulty of adjusting the curvatures in groined vaults when the springing and elevation of the lateral, transverse, and diagonal arches are on the same level, but the spans different. In circular arches this difficulty is accommodated by tilting them at the impost, or making the diagonal ribs a segment less than a semicircle. With the introduction of the pointed arch this difficulty was greatly diminished; "but notwithstanding the possibility of making pointed arches of any proportion of height and span with their centres of curvature upon the impost line, it will be found that the old expedient of placing the centres of curvature above or below the impost line, for the better adjustment of these arches, was still retained in pointed architecture until the four-centred arch was brought in. I shall proceed to examine this more at length, since it involves so much of the characteristic appearance of these vaults." This characteristic appearance in original Gothic vaulting arises from the curvature of the ribs, (as Professor Willis makes it evident by numerous examples,) being always arcs of circles, and he comments very justly and severely on the erroneous but common method of projecting the diagonals of Gothic vaults by ordinates, to the utter destruction of the mediæval character of the work—"This is the genuine principle of the Roman and Italian groined vault, but is altogether foreign to the principles of Gothic architecture, in which every rib should spring as a separate and independent arch, and in which the elliptic curves produced by this method are totally at variance with the characteristic forms of the style." This mode of projecting the diagonals was taught by De l'Orme, but he was perfectly aware that it was inapplicable to Gothic vaulting, of which, as a matter of curiosity, he gives a description, making every rib perfectly independent of the rest in its curvature. This stupendous blunder is therefore due to more modern times. Even in genuine Gothic vaulting the effect becomes comparatively vapid after the introduction of the four-centred arch, owing to the regularity with which all the ribs start at the same angle from the impost.

The third section is of great practical utility, and treats of projecting the forms of the stones in decorative vaulting, especially of such as form the converging points of the liernes. The subject is complicated, and not to be made intelligible without reference to the diagrams by which it is copiously illustrated. The liernes in decorative vaulting form a variety of elegant figures about the centre of the vault, of which a star shape is the most common. Hence Professor Willis has given to one class of this description of roof the name of *stellar vaulting*, which very happily expresses its character. The dependence of the designs of these vaults upon geometrical construction is well illustrated, the form sometimes coming out in the solid when its existence would hardly be suspected from a mere view of the plan; and on the other hand being sometimes symmetrically laid down, and disappearing under the effects of the perspective. As vaulting advanced in complexity, a revolution took place in its mechanical construction. This occurred when the compartments of lierne vaulting became so numerous, and consequently so contracted, "that it was found simpler and stronger to work the small portions of panel surface between the branches of the boss stones out of the same block, than to cut them away and drop in the panel afterwards. Then the bosses, from the increasing complication of the patterns, began to approach so close, that it was worth while to take the pains to make them meet, and thus the crowns and ridges of the vaults came also to be built solid. Lastly, the solid construction was extended to the entire vault, and so by gradual degrees the mechanical and decorative construction of the vault, which began by being identical, ended by becoming totally different." This brings us to the subject of section 4—*fan vaulting*.

We must here again refer to the work and the diagrams, in which is developed the method by which the complicated forms of the stones in these remarkable structures may be accurately modelled. The characteristics of fan vaulting are thus described:—

"The pattern of these vaults is always a kind of tracery of the same class as the perpendicular tracery which at that period occupied

the heads of windows or the surfaces of walls, the only difference being that the mullions, instead of being parallel and vertical, are curved, and radiate from an impost. Instead, therefore, of the horizontal transoms of windows, we have level circles intersecting the ribs at nearly equal distances, and intermediate rays or ribs are inserted between the principal ones. The panel spaces into which the surface of the vault is thus divided are furnished with arch heads and foliation, exactly as the similarly produced panels are ornamented in the tracery of windows.

"I have already stated that in the lierne vaults a star pattern is commonly found, which radiates from each impost in the same way as the fans of the present class of vaults. The difference between the star and the fan is, that the star is formed of ribs, which may be and often are of different curvature, and the rays of the star of different length, but so skilfully arranged with regard to their solid effect, that although irregular upon the plan, this irregularity is not offensively perceived in the complete work.

"The fan is, on the other hand, formed of ribs strictly of the same curvature and elevation, and its outline is bounded by a horizontal circular rib instead of the zig-zag line of liernes in the former vaults by which the rays of the star are pointed. The effect of the fan is that of a solid of revolution, upon whose surface panels are sunk; the effect of the star is that of a group of branching ribs. This difference of character is assisted by the mode in which the mouldings are disposed in the two cases. In the older vaults a vertical plane upon the plan line of every lierne or rib divides it into two symmetrical halves; but in the fan vaults the moulded rings and arch heads are all perpendicular to the surface of the vault.

"In fan vaults the quantity of decoration is so much increased, and its parts become so small, that it is no longer practicable to frame the tracery of these vaults on the rib and panel system with liernes and boss stones, and consequently the portions near the crown of the vault, where the decoration is compressed and crowded, are always constructed of jointed masonry. But the branching ribs below the first series of arch heads are still built of long stones filled in with panels, and the *tas de charge* from whence the ribs spring is also laid in level courses as before. There are a few exceptions to this general description; for example, the vault of Henry the Seventh's Chapel, which, however, differs in many other particulars from these fan vaults, and will be separately described. It is entirely constructed of jointed masonry without panels. Also the vault of Islip's Chapel at Westminster is a real fan vault, but without any mixture of rib and panel work."

In illustration of this portion of the subject, the author has described the vaulting of the chapel at the east end of Peterborough Cathedral, the construction of which is identically the same with that of King's College Chapel vault, on a smaller scale, but of very superior execution; that of Henry VII's Chapel; and that of St. George, at Windsor, the latter being not a real fan vault, but "a wagon vault, whose lateral or transverse vaulting cells enter it below its crown." These descriptions are accompanied by three elaborate engravings, exhibiting the construction in the most perfect manner, by isometrical views of the upper surfaces. There are also plans and sections of the same subjects, and of the beautiful lierne vaulting in the cloister at Canterbury.

An appendix adverts to some very striking effects produced by modifications in the forms of the spandrels in the vaults of the cloister at Norwich, upon which it is unnecessary to dwell, as the paper from which it is transferred was read lately, and reported in the *Journal* at the time.*

We hope enough has been said on this admirable essay to recommend it to all who profess the study of our mediæval structures, whether as architects or antiquaries. The information it contains addresses itself to both classes, and if it were for the sake of this paper alone, the volume ought to be in the hands of every one interested in Gothic architecture. We cannot conclude better than in the author's own words, hailing with the most sincere satisfaction the promise which he holds out.

"In conclusion I must beg it to be recollected that I offer this paper as a sketch of an investigation, for the completion of which I request the assistance of the members of the Institute in the collection of facts and examples. I have endeavoured throughout to show from evidence the existence and employment of geometrical methods from a very early period, and have attempted to restore some of these methods. I have also ventured to assert the importance of certain forms and arrangements in imparting character to the buildings in question. The necessary limits of a paper of this kind have prevented me from introducing several topics which may appear to belong to the question in hand. Thus I have said nothing respecting mechanical

* See p. 98—*Journal* for March, 1842.

principles, and have confined myself to form and arrangement. But it appears to me, from examination of the works of the Middle Age architects, that the latter considerations had an infinitely greater influence upon their structures than the relations of pressure, then very little understood, and about which they made manifest and sometimes fatal errors; so that this omission may be fairly allowed, or at least the discussion of this part of the subject may be carried on separately. Also with respect to the elaborate and beautiful class of vaults which I have termed Lierne Vaults, I propose, at some future time, to offer to the Institute a supplementary paper containing many observations upon them, and probably additional remarks upon the entire subject. Lastly, since the methods which I have explained in this paper have been for the most part elicited from an examination of the existing vaults, it may be worth while to compare them with those that are recommended and taught in the books of stone-cutting already quoted and referred to, as well as with modern actual practice."

Mr. Poynter's paper "On the contemporary styles of Gothic architecture in England and France," supplies what has long been a desideratum. Considering the novelty and importance of the subject, we could wish, as we have already hinted, that it had been treated more at length, but we must accept it according to the intention of the author, who professes no more than some observations "of slight texture, as an index to more diligent inquiries." A chronological table (which, with some account of the paper, was inserted in the *Journal* at the time it was read,) exhibits a parallel of the styles of French Gothic, as distinguished in the treatise of that eminent and candid antiquary M. de Caumont, with those of the English, as divided and designated by Rickman, and the characteristics of each are rapidly traced in the essay. It is a masterly sketch, like the illustrations by which it is accompanied. We are not aware that any representation has ever before been given to the public of the magnificent tower at Verneuil, a view of which forms the frontispiece to the volume. The other engravings appended to this paper are, the eastern view of the cathedral of Coutances, and the doorway of a small church near Dreux. The latter is designed to illustrate a peculiar form of pediment common in the Tertiary or Flamboyant Gothic of France, but unknown in England, and a custom in French architecture of making the portals of the smaller churches occupy the whole height of the centre compartment, "an arrangement which producing an excellent effect by its simplicity, may," as the author pointedly observes, "reprove a practice too common in modern Gothic architecture, of executing great designs on a small scale, and little designs on a large one." Summarily as the subject is handled in this paper, it will be found a most useful chronological guide to the student who is about to examine the mediæval architecture of our neighbours.

One of the marked peculiarities of foreign Gothic, glanced at in a few words in the last paper, forms the subject of the next, in which Professor Willis has treated of "The characteristic interpenetrations of the Gothique Flamboyant." The fanciful intricacy of parts which characterizes the later continental Gothic, and distinguishes it from our contemporary perpendicular style, has given rise to the excessive employment of interpenetrating surfaces. In English Gothic, examples of this sort of composition are confined to the interference of adjacent architectural members, and even these are not common; but in the Flamboyant style, members are introduced and accumulated one upon another, for the express purpose of showing interpenetrations. "Thus two different bases may be given to the same shaft, or even two or more different turrets with pinnacles may be placed in an identical position on the plan, and made to interfere and interpenetrate throughout their entire height, from the base upwards, in a manner that defies description, and can only be illustrated by drawings."

We shall, therefore, not attempt to follow the various specimens of interpenetration which are displayed in the diagrams, but merely notice the principal illustration—a doorway in the Cathedral of Nevers, flanked by pinnacles, or rather heaps of pinnacles, the composition of which appears at first sight to set at nought all attempt at developement or classification. Mr. Willis has, however, unravelled this strange tangle of architectural details, and has shewn its complicated effect to be produced by "the co-existence upon the plan of three distinct architectural members, each having its own set of mouldings." These members, which are represented in the plate both combined and separate, are two square shafts with their separate pinnacles, caps, bases, &c., set diagonally, so that the angles of the one pierce through the faces of the other, and these are enveloped in a cylindrical column, round which are twisted spirally four shafts, each with its separate cap and base.

(To be concluded in the next Journal.)

Memoirs of the Literary and Philosophical Society of Manchester, Second series. Vol. VI. London: John Weale.

THIS Society has long stood eminent for the value of its papers, and the high character of several members for the extent of their literary and scientific attainments; it therefore affords us much pleasure to receive the present volume, which contains 23 papers, several of which are of the utmost value, both to the architect and the engineer. The researches and able experiments of Mr. Fairbairn on the strength and properties of cast iron, are particularly deserving of a careful perusal. This paper contains "a laborious inquiry into the transverse strength of cast iron from various parts of the kingdom, and also an extended investigation into the less cultivated field of their relative values, as regards their adaptation to the arts." From this paper we hope to have an opportunity of giving some extracts, and a more extended notice. There is also another paper by Mr. Fairbairn equally valuable—that on the strength and properties of anthracite cast iron. He first makes some observations on the nature and properties of anthracite used for the melting of iron, in Wales, France, and America; and after detailing several experiments on the strength of iron, he concludes by saying—"I consider the use of anthracite coal rather favourable than otherwise to the manufacture of iron; and provided some well conducted experiments were made to ascertain the requisite proportions of flux and ore to this description of coal, much might be done to improve the quality of the iron, and to bring into useful operation a valuable and important mineral production."

In last month's *Journal* we published Mr. Greg's interesting paper on Sepulchral Monuments; by the same author we have another paper, entitled "Remarks on the Mural Architecture of remote ages." There is a paper containing some observations on Sculpture by Paul Moon James Esq., in which he takes a review of the works of our modern sculptors; and there is also one containing a curious inquiry into the origin of the "Babylonian arrow-headed character," by Mr. James Nasmyth, which may be read by the antiquary with much interest. From the press of other matter, we are precluded from giving a more extended notice of this varied and extended volume, but we shall not omit future opportunities of turning our attention to it again, by giving a few extracts from some of the papers which are connected with the profession.

A Series of Diagrams Published by the Society for the Diffusion of Useful Knowledge. Drawn on Stone by H. CHAPMAN, and Printed in Colours by C. F. CHEFFINS. Part II. London: Chapman and Hall, 1842.

THESE diagrams not only maintain the high character with which we hailed them on their first appearance, but give an earnest of possessing even more extended utility. In the present number the delineation of the mechanical powers is continued, and is accompanied with the section of a fire engine. We should suggest that the value of the work to students would be increased if each plate were accompanied with descriptive letter-press, explaining the power of the screw, pulley, &c., as applied in the diagrams.

A Treatise on Engineering Fieldwork, and Levelling. By PETER BRUFF, C. E., A. Inst. C. E. London: Simpkin and Marshall, 1842.

STUDENTS have no cause to complain of the want of books on surveying, but of the *embarras de choix*, for among so many works they must certainly find themselves at a loss. The book before us forms the second part of the second edition of Mr. Bruff's treatise, with many valuable additions and improvements. When it is complete, we shall notice it at some length.

New Cemetery.—We understand that the designs for laying out the new cemetery, on the lands of Bangholm, recently fued from the Governors of George Heriot's Hospital, have been considered by the committee of the cemetery company, who have awarded the first premium to Messrs. Cousin and Gale, architects, Royal Exchange, and the second to Mr. Thomas Taylor, architect, Mackenzie Place—all of this city. There were 17 designs sent for competition, including several from London; it therefore reflects great credit on our resident artists, that their works should have been preferred, all but unanimously, in such a competition; and there could be no favouritism, for the names of the successful competitors only became known after their designs were preferred. That for which the first premium is awarded is in the Gothic style, and includes a chapel wherein the usual services of Episcopalians, at the interment of the dead will be performed when required. —*Edinburgh Observer.*

ANSWER TO THE REVIEW OF MR. HAYDON'S LECTURE ON FRESCO.

SIR—It is impossible not to be gratified by the tone, temper, and kindness evident in your review of my lecture on fresco. There are one or two mistakes as to facts, which are easily corrected, and one or two as to my theories of art, which it is but just you grant me an opportunity of refuting. With these exceptions, the article is so gentlemanly in its feeling, so totally opposite to the scurrility of the greater portion of the daily and Sunday press whenever my name comes under their consideration, that I was pleased and startled.

At one time the whole of the press aided and supported me, and I can only attribute the change to this—that for the last 25 years the students have been brought up to consider me a monster and a rebel; that all students in art form literary connexions in their youth; that the young literary men branch off into reporters, critics, or editors; that they have carried their early impressions with them, and that they consider it a moral duty to drive Haydon out of the art, or off the face of our common mother earth, just or unjust. Be assured, therefore, to meet with *justice* is something so novel, that before beginning my reply, your readers must pardon my allusion to it.

The assertion that my quarrel with the Academy was a school-boy quarrel, and that it originated in some one saying "*Haydon's pictures to the coal-hole!*" is an entire delusion; and the President before the committee of 1836, pale and exasperated, found it anything but a "school-boy affair." But now is not the time to recur to so painful a subject: it will be time enough to return to it when the present noble views of Prince Albert, the Commission, and the Government are baffled, they cannot tell why; when a series of portraits are recommended, as most suitable to British taste, in the Houses of Parliament, instead of historical designs; when fresco is given up, and cartoon drawings become a joke;—*till then*, let the Academy question rest, let the Royal Commission get experience, and let the public patiently wait the unravelling this Gordian knot!

The reviewer says, "I hold high art to consist in the selection of the *best* parts, of the *best* models, and in their *union*." So far from it, that in my lectures I have always held up to ridicule Pliny's assertion that such was the practice of Zeuxis at Crotom, when he painted a Helen for the Crotoniates. The selection of the best model, and rendering the parts defective in harmony with the parts not so, is not selecting different parts from different models, which never can harmonize at all. I have ever held high art to consist in restoring man, woman, child, and animal, to the essential physical perfection of their species, cleared from all consequences of accident and disease, as God first created them, more or less, according to the style, for art is divided into epic, dramatic, and historic, and in the illustration of the epic by the species—man—the instrument of illustration, must be as abstract as the style. Man is *here* supposed to be above the degradation of human emotion, or historic fact. The perfection of his body is an emblem of the supposed perfection of his soul; the *one* must be as much above human frailty as the other; but in the dramatic, the instrument used will bear some deterioration of form from the high standard of the epic, to suit the individuality of any character which is affected by human passion; whilst in the historic, the agents may and must be disfigured by the localities of individuals known to have possessed such characteristics, however inconsistent they may be with a human form in the abstract. The one arm of Nelson—the little figure of Napoleon—and the hump of Richard, are as essential to the historic, as they would be offensive to the epic. *This* is Haydonism, if you please, and not the mistakes of my reviewer.

My kind reviewer wonders at my rejecting David and the *lower* Greek, and adopting Theseus and the *elder* Greek! and I wonder he classes the two together, in the same thought, the same breath! What? class the principles of vitality, action, repose, flexion, extension, compression, gravitation, flesh, bone, and tendon, the characteristics of the *elder natural* Greek, as visible in the Ilyseus and Theseus, with the systematized deformities and pedantry of the *lower unnatural* Greek? The principles of Phidias (the *elder* Greek) are the principles of the Creator, and Phidias may be considered without profanation as the representative of the principles of the Creator on earth, as far as conveying the effect of vitality by inert marble, in his imitations of the form and actions of man, can entitle him to the immortality; and, therefore, the perfection of sculpture, as visible in the Elgin marbles, is not inconsistent with the perfection of painting when form is considered, and it may be laid down as an axiom in painting, that when the nature, simplicity, and principles of the Elgin marbles are considered inapplicable to British art, British art will be in a condition of inextricable mannerism of either vulgarity or con-

ceit. The Elgin marbles are not Greek, they are *human*. The reviewer says the *Πανταλον* or the *Πανταπισταν* are not sound principles of art. Certainly not, exclusively: they are the *seasoning* of the *Πανανθρωπινον* (the all-essential). Convey the all-essential by the all-beautiful, but not at the expence of the all-essential.

"Another of Mr. Haydon's theories," says he, "is the sovereignty of Greek painters; that not a fragment of their works exists *is no argument against enthusiasm*." This is a sort of insinuation I have all my life suffered from, viz., that my convictions proceed from enthusiasm, and, therefore, have no ground; whereas my enthusiasm has always been the *consequence* and never the *cause* of my conviction.

If the descriptions of Pliny of the mode of Apelles to produce tone by glazing apply to the Venetian school, (which produced tone by glazing,) where is the want of reason in saying Apelles coloured like the Venetians, and must have done so? If Quintilian says Zeuxis discovered the principles of light and shade, light and shade they must have had; if a bull was painted the head coming out and the tail going back, they must have had foreshortening: so of their expression, composition, and perspective. Of their drawing we are certain, and of their execution by touch there can be no doubt.

The reviewer concludes by ridiculing my principle of adorning the Houses of Parliament, and calls the subjects allegorical! I advise the illustration of "the best Government to regulate without cramping the liberty of man," by a series of historical subjects from the history of the world. Surely the allegory is only in the abstract principle; but the illustration of the horrors of anarchy, democracy, despotism, and revolution, and the blessings of law, justice, and monarchy, by positive historical facts, with statues between each fresco of the great men who have caused the principles to be established, is anything but an insipid allegory without meaning or sense. "Nature we want, and nature we will have," says my friend (for I am sure he is so): then comes the question, what is nature? Queen Elizabeth eating beef-steaks and drinking ale for breakfast, the pathetic murder of the princes in the Tower, and St. Augustine preaching Romanism to the Britons, are all equally nature, but nature under different views. To conclude; the "*cave canem*" is not as to Haydonism, but as to what will be much more dangerous to fresco and sound design, viz., "The ale and beef-steaks of art," under the pretence of nature.

With every apology,

B. R. HAYDON.

London, July 8, 1842.

REMARKS ON THE "DESCRIPTION OF THE PERMANENT WAY OF THE SOUTH-EASTERN RAILWAY."

In this age of discoveries, in this truly *patent* century, the minds of so many men, both theoretical and practical, are engrossed by an ambitious zeal of improving the inventions of their predecessors, and by the wonders of their brains of obtaining the reputation of a Smeaton, a Watt, or a Stephenson, that we must not be astonished to find amidst such a host of competitors some advocating schemes stamped with absurdity. It would really be a useful lesson to some of these ardent aspirants for fame to read the list of patents taken out during the last forty or fifty years: it would serve to cool their temperament to find how few have derived any profit from their inventions. That men imagining themselves possessed of the *lump* of invention (I am not sure whether phrenologists admit of such an organ,)—having neither the advantage of a good theoretical education nor the experience acquired by years of practice—should commit the grossest mistakes, both in principle and mechanical combination, is not astonishing, neither should we wonder that purely practical men should fail in theory, or pure theorists in practice; but when we find men possessed of the greatest talents, of great experience and of good theoretical knowledge, at times advocating principles false alike in the eyes of the practical and theoretical man, it only shows with how much caution we ought to proceed in the path of discovery, and how necessary to the establishment of sound principles it is to have a journal like yours, open to the discussion of subjects connected with engineering. These remarks have suggested themselves to me in reading the "description of the permanent way of the South-eastern Railway," which appeared in your journal for this month. I had previously often heard that Mr. Cubitt, who, as an engineer of great abilities and extensive practice, must ever be regarded as a high authority on engineering subjects, maintained the superiority of the triangular to the rectangular sleeper, but on what principles, previous to reading Mr. Pope's description and the report of the conversation which ensued amongst the members of the C. E. Institution, I could never ascertain. It is clear that their superiority in point of *ultimate*

economy cannot be determined until they have been tested by some years' use. With regard to first cost, it appears that the advantage of the triangular sleeper is trifling; indeed, if we had not Mr. Cubitt's word to the contrary, I should have said that it was inferior even in this particular. Any other advantage resulting from the use of the triangular sleeper, I certainly cannot conceive, except that the ballast can be more easily rammed, in this case no doubt a very great advantage, as from the form of the sleeper it will evidently require that operation very frequently. I shall, however, quote from the description, and if any of your readers can explain to me the other advantages stated, I shall consider it a great favour:—

"The sleepers are of Baltic fir, and are formed by a square balk being diagonally divided so as to cut out four triangular sleepers, which are laid down with the right angle downwards, which form as much bearing surface as one of twice the cubic contents cut out as half a balk, in the usual manner. The advantages arising from this form in the economy of timber, the facility of packing, and the improved drainage of the ballast in contact with the sleepers, are pointed out, and the apparent disadvantage of the tendency to act as a wedge is combated, by showing that the inclination of a right angle exceeds the limits within which the principle of the wedge obtains."

No doubt a sleeper of this form has as much bearing surface as one of twice the cubic contents cut out as half a balk, but it should also be recollected that any weight passing over such a sleeper will exert a pressure increased in the ratio of the square of two to unity, as can easily be seen by resolving the weight in directions perpendicular to the inclined surfaces of the sleepers; and it must also be noticed that this increased pressure on the ballasting is exerted in the worst direction possible, that is, laterally, where there is nothing to retain the ballast, whereas with the common rectangular sleeper the pressure is vertical, and after the first year the ballasting becomes consolidated, and requires comparatively very little ramming. I think, therefore, that for the first year it may be less expensive to keep a railway laid with triangular sleepers in proper order, but that after the first year the "triangular system" will be found inferior not only in point of expense, but also of solidity and firmness. I should certainly be much pleased to learn from Mr. Pope how "the inclination of a right angle exceeds the limits within which the principle of the wedge obtains." Perhaps Mr. Pope could point out these limits: I am sure your readers would also be highly pleased if Mr. Horne would publish an account of his series of experiments on the strength of timber, for the results are quite extraordinary. If these remarks appear to you worthy of being inserted in your valuable journal, you will oblige me by doing so.

Dublin, June 10, 1842.

Yours truly,

J. F.

BOOKMAKERS' DESCRIPTIONS.

SIR—Very much to my dissatisfaction, I find that your Journal has prophesied truly with regard to the "Memorials of Cambridge," for there is nothing that amounts to description at all of Cockerell's new building for the Public Libraries, &c; nor is the view of it as it will appear when completed shown so as to enable one to make out from it what the design really is, the principal front being so exceedingly foreshortened that little more than the projecting parts of the elevation are shown. Owing to the portico being taken quite on its flank, one peculiarity—either oddity or original idea on the part of the architect—is not at all discoverable, namely, that it has a central column, consequently no central doorway!—a circumstance in the design so very important as well as unusual that, instead of being concealed, it ought to have been indicated as plainly as possible. At any rate, if concealed in the graphic description of the building, it ought to have been pointed out in the letter-press one; but the latter turns out, just according to your Journal's prediction, to contain no description at all, although the wrapper of each No. of the work promises "descriptive accounts of the buildings." Perhaps this may have been a misprint on the wrapper of the first No., which has unluckily not been rectified; and it surely must have been intended that we should read "with historical but no descriptive accounts, &c."

Of the two editorial M.A.'s, one an Esq. the other a Rev., neither, it seems, knows anything whatever of architecture, or is capable of even describing a building; yet surely one of the two should have been chosen for his competency in regard to drawing up the "descriptive accounts." As it is, it certainly would have been better had no promise whatever of the kind been held out to purchasers. Yet even without positive promise to that effect, many would, like myself, naturally

expect to find the buildings shown in the plates explained, if not commented upon, in a tolerably full and satisfactory manner, in the letter-press, which is certainly not done here, save in the solitary exception specified by your own reviewer, and which is, therefore, rather an unfortunate one as far as the character of the "Memorials" is concerned, because it renders all the more striking the absence of similar explanation and description in the other subjects. For not again describing what has been repeatedly spoken of before by others, and rendered quite familiar to us in consequence of having been treated of in a variety of publications, there may be some excuse; but very far different is the case with regard to what may be called "unedited" buildings. One of these is the "Pitt Press," to which may be applied the writer's own words, who tells us, "We possess but a very obscure and defective account of the early history of printing in our University," for his account of the structure is equally "obscure and defective." All that we gather from it is that the building was designed by Mr. E. Blore, that the first stone was laid in Nov. 1831, and that it was opened in April, 1833. To be sure we are favoured with a copy of the inscription on the foundation stone, with the names of the nobles who took a part in the highly important ceremony of placing it, "Totâ inspectante et plaudente academia," which last is merely a bit of solemn bounce—a silly white lie, that contradicts itself, because, even if such were the fact, it could not possibly have been recorded upon the stone until after the ceremony. A grosser blunder—a more egregious practical Hibernianism—perhaps was never made; and as Mr. Le Keux's editors had not the nous to discover it, they have very innocently shown up that exquisite specimen of University sapience, and swallowed the bull, without making "any bones" of it. As to Mr. Le Keux's own share in the work, I suspect it to be very small indeed, for although his name is attached to the plates as the engraver, none of them seem to have been even touched by him; else, if they really are his work, they manifest a very great falling off from his former excellence.

I remain, &c.

T. W.

ROYAL ACADEMY EXHIBITION.

SIR—Observing a letter in your July number, under this head, containing complaints from *The Architect* of a design, the perspective view of which was forwarded by him from a distant county for the purpose of being submitted to the Council or Hanging Committee for exhibition this year, and which, in due time, was reported as having been admitted, and afterwards did not appear on the walls of the Royal Academy, and having been treated in precisely the same manner myself, I deem it right to mention the fact, in hopes that some of your numerous correspondents may be able to suggest some reasonable excuse for such indecision on the part of the Hanging Committee.

When I hear of letters having been written by the officials of the Royal Academy to some architects who had sent works "obviously varying from the regulations" laid down by the Council, although "the porters are instructed not to receive any" such, in order that, even after the last of the two days "announced in the public papers for the reception" of "works intended for the annual exhibition," they might have an opportunity of complying with those regulations; when I find that upwards of 40 of the works catalogued under the head of ARCHITECTURE in this year's exhibition bear no relation whatever to that noble art; and, above all, when I find such a *mountain-in-labour-like* title as "No. 1011, Raising the monolithic granite obelisk between Fleet Street and Ludgate Hill, on the morning of June 26, 1833," and then see the *mouse-like* production which the reviewer in the *Gent's Mag.* very pithily describes as being the representation of "five labourers, with the aid of a triangle and a pulley, performing the Herculean task of setting this vast obelisk on its pedestal," I confess myself quite at a loss to account for the bad faith kept by the Hanging Committee with your correspondent *The Architect*, and with,

Sir,

Yours, faithfully,
Ego quoque.

London, July 9.

Turnpike Roads.—In 1818 there existed in England and Wales paved streets and turnpike-roads to the extent of 19,725 miles, and other public highways 95,104—making altogether 114,829 miles. From the report of the lords of the committee upon turnpike trusts, it appears that in the year 1829 the extent of turnpike-roads in England was 18,224 miles; Wales, 2631 miles; Scotland, 636 miles—making a total of 25,511 miles.

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.

LECTURE VII.—ON CURVES OF RAILWAYS.

This lecture was devoted to the consideration of curves upon railways, and Mr. Vignoles pointed out the principles on which should be compared the economy and advantages to be obtained by the adoption of curves, with the inconveniences attending on them; the saving of expense in formation, earthwork, bridging, &c., by curving round natural obstacles; the advantages of attaining a more level line, avoiding interference with valuable property, or approaching towns, mineral or manufacturing establishments, &c., all entering into the former—the practical inconveniences of additional resistance to motion and retardation of velocity to ensure safety being the set-off; and, among other elements, it was stated that the breadth or gauge of the railway affected the calculation. The Professor then showed that along very wide valleys, through champaign countries, and where the grounds undulated, so that the ridges, dividing the water courses, were successively crossed by the railways at right angles to their general direction, the saving by lateral deviation would seldom be material, and consequently, that the curves may be laid out so flat as to be practically equivalent to straight lines—the “*accidens de terrain*,” to use a French phrase, being, in such districts, to be overcome by cutting and filling, to the extent justified by the importance of the line and traffic, or by the introduction of undulating gradients, somewhat approximating to the natural surface of the country. But in tracing a line of railway along the sides of hills bounding narrow valleys, particularly where the main valley is broken by lateral rivers, then the economy from curving becomes very great, and the introduction of curves to the greatest possible extent, consistent with safety, is allowable.

Mr. Vignoles then went on to consider the various means employed to obviate the practical inconveniences arising from curves on railways. He began by explaining the peculiar distinction in make between carriage-wheels and axles constructed for running on railways and those for common roads—in the former the wheel being keyed fast to the axle, and both moving round together—in the latter the axle being fixed to the carriage, the wheels only moving round. Many attempts had been made by engineers to give the railway vehicle the advantage which the road carriage had of turning with facility and safety round sharp bends, but in vain, as the wheels always got off the rails laterally, at even moderate velocities; it was only on the old tramroads that the wheels were loose on the axles. Railway wheels being thus fixed to the axles have the tendency to move on a straight line, so that on the occurrence of a curve the effort to continue in motion in the direction of the tangent of that curve creates a certain degree of resistance, as the wheels are only kept upon the rails by the flanges pressing against the inside edge of the outer rail of the curve. The Professor then entered into a number of technical details, which he illustrated to the class by diagrams, explaining why the flange of the wheel had now, by common consent, been placed on the inner side of the periphery of the wheel rather than on the outer side; and also the reason for allowing a certain amount of play, being the difference between the gauge of the rails and the gauge of the wheels, and the manner and cause why the rim of the railway wheel is made somewhat conical—that is, the wheel, instead of being quite cylindrical, is really the frustum of a cone—stating at the same time, the rule for giving the proper “cone” to the wheel, being dependent on the *minimum* radius of curvature on the line to be travelled over, and the *maximum* velocity. In general, the “cone” was stated to be about one-seventh of the breadth of the rim of the line, giving about one inch for the difference of diameter of the wheels at their inner and outer edge, for, when carriages are passing round a curve, the wheel and axle, being connected, roll together as a rigid body, and require the contrivance of the “play and the cone” to prevent too much lateral friction of the flange, and to get the wheel round the curve without dragging. Mr. Vignoles then showed that on the ordinary railway gauge of 4 ft. 8½ in., and in the 3-foot wheels, the above amount of cone and play would be sufficient to meet a curve of only 200 yards radius, which is greater than any which ought to be laid down on a travelling line for high speeds.

The centrifugal force due to the velocity of the carriage was next to be considered. As before stated, its tendency in moving round a curve is to keep a tangential course; this force may be accurately computed (being dependent on the velocity of motion, weight of the carriage, and the radius of curvature) by well-known formula, whence is deduced the fractional part of the weight of the carriage, representing the centrifugal force. The Professor gave the formula, and worked it out on a supposed velocity of something more than 17 miles per hour, or about 25½ ft. per second, on a curve of 200 yards radius, whence the centrifugal force was found to be 1-30th of the weight of the carriage. Mr. Vignoles quoted the following rules—viz., “multiply the square of the velocity in feet per second by the gauge of the railway, and divide the product by the accelerating force of gravity, multi-

plied by the radius of curvature in feet,” which gave an expression, which, though not the fraction of the weight, was what would do very well for practical and ordinary purposes; it was the height which the outer rail of the way should be elevated, to counteract the centrifugal force, and prevent the wheel flying off at a tangent to the curve. He then stated M. de Pambour's more strictly mathematical, but more complicated, rule for obtaining the same amount of elevation of the outer rail, and showed the table of results calculated by that engineer and by Mr. Wood, of which we only give the extremes, by which it appears that, supposing it safe to encounter so sharp a curve as one of 250 ft. radius, at the rate of 30 miles an hour, the outer rail of the way must be elevated 12 in.; but for a radius of 5000 ft., or nearly a mile, at the rate of 10 miles per hour, the requisite elevation is only 1-16th of an inch. Having elevated the outer rail, the axle of the carriage, resting on the two rails, gets such an inclination as will produce on the load a gravitating force inwards equal to the centrifugal force outwards; and there will neither be any tendency in the carriages to upset or to press the flanges of the wheels against the rails. The rails once laid, if the carriages run slower than the calculated rate, the centrifugal force is overbalanced by gravitation, and the flanges of the wheel press the inside rails; if quicker, the contrary effect takes place, and the flanges press against the outer rails, so that some medium rate of travelling must be fixed on; and, as the slow trains are in general most heavily laden, any increase of friction has a more powerful effect of retardation than will occur to lighter loads moving at greater speed. Mr. Wood, therefore, advises that the outer rail should not be elevated more than will compensate the centrifugal force produced at the slower rates of motion with heavy trains. Mr. Vignoles then forcibly illustrated the practical effects of neglecting these rules.

He then entered on the subject of laying out curves on the ground, by a succession of set-offs at the end of each length of any given measure—the set-off being calculated from the radius of curvature, considering the given measure (say a chain length) as the side of a circumscribing polygon; and, on the large scale, and practically, a number of these sides of a polygon become the segment of a circle. Mr. Vignoles gave a simple approximate rule for finding the set-off from the radius, or the reverse, by “divide the number 792 (the number of inches in a chain) by the radius in chains—the quotient is the set-off per chain in inches.” Thus, the set-off per chain for a curve of a mile radius is 9.9, or, in round numbers, 10 inches. When the curve is of less than one mile radius, it is advisable to make the set-off by half-chains. It was observed incidentally by the Professor, from the same rule, the set-off due to the curvature of the earth was, in round numbers, about eight inches per mile, and hence had arisen formerly some curious engineering mistakes, from supposing that a horizontal line was a tangent to the earth's surface; and, in setting out canals, an inclination of eight inches per mile had more than once been given to the water line, while it was imagined it had been laid out for a dead level. In conclusion, Mr. Vignoles mentioned that some further observations on curves would occupy the next lecture.

LECTURE VIII.—ON CURVES.

In continuation of the subject of curves, Mr. Vignoles explained that in many cases it was impracticable or inconvenient to apply, on particular ground, the approximate rule given in the last lecture, of setting out curves chain by chain, or other short lengths, making each the side of a regular polygon, the set-off being constant. In that method the given length was strictly a secant, and not a tangent, to the curve. Another formula was more generally applicable, and sharp curves on hill sides, through thick woods, had been quickly and accurately set on therefrom. It was this;

$\text{offset} = \text{radius} - (\text{radius} - \text{tangent})^{\frac{1}{2}}$; the demonstration of this was given, and illustrated by a diagram. For the field, tables calculated beforehand, for the greatest number of usual curves, should be prepared; but, on the occurrence of any peculiar cases, the calculation could be very readily made, with the help of a pocket table of natural sines. The Professor then recapitulated some of the leading points that had been gone over in detail at the last lecture, observing that on the three principal expedients for counteracting the injurious effects of curves, the usual measurements might be easily remembered—viz., half an inch for the “cone” of the tread of the wheel; one inch as a *maximum* amount of “play” of the wheels between the rails (it being disadvantageous to allow too much play); and one inch for the extreme elevation of the outer rail in laying the way, that being the measure due to a velocity of 25 miles an hour, on a curve of half mile radius. Mr. Vignoles then observed that the “cone” being given to the wheels, on account of the curves, when the line of road was perfectly straight, this conical formation of the tyre was not required, and the general disadvantage of such a form of wheel, not bearing upon the whole face or upper button of the rail, preponderated. It had, therefore, become customary to incline the rail, to meet the cone of the wheel, and this should always be done, both on straight lines and on curves whose radii are not small. This inclination of the surface of the rail is obtained by casting the receiving chair accordingly on rails; having a continuous bearing on longitudinal sleepers, or

bearing direct on cross timbers, without the intervention of chairs, the wood is cut to the requisite angle; or the inclination is sometimes given to the rails in passing through the rolls. Without this precaution of inclining the bearing surface of the rail to meet the cone of the wheel, the edge rapidly wears, and the laminae of iron peel off in strips, more or less, according to its quality, and there is no more critical test of the perfection of rolled iron rails than the manner in which the button edges go through this ordeal. With the above precautions of "cone," "play," and elevation of the outer rail, the resistances opposed by curves to a single carriage may be considered to be practically annihilated; but when the trains become very long, there must, of necessity, be a considerable lateral action and grinding, from the change of direction of the original drawing force through a number of carriages; but Mr. Vignoles stated that, although no conclusive experiments had been made to show the exact amount of resistance from this cause, his own observations and experience led him to conclude that the degree of curvature on railways might be safely extended further than they have hitherto been laid down on principal lines.

Mr. Vignoles referred to former observations of his, that the public would be better accommodated by more frequent departures of smaller trains, and that with such trains the curves would be of still less importance, adding that it could only be by the introduction of greater curvatures to save expense; and, as he had repeatedly argued for the same reason, by the adoption of steeper gradients, that the benefits of railway communication could be extended through many districts, and to the more distant parts of the country, as on the most economical principles of construction. Mr. Vignoles referred to the report of the Irish Railway Commissioners, and to the works of Mr. Wood, M. de Pambour, Lieut. Lecount, and other writers, for further details on curves, observing, in conclusion of this part of the subject, that where curves are so quick as to require it, especially in crossings, the additional precaution of guard rails becomes expedient.

In adding a few words on the subject of coupling carriages together in a train, the Professor insisted strongly on the draw-boys being always in the centre, and observed that, as a general rule, the connecting links should be screwed up as stiff as possible consistent with the curves of the railway, as otherwise the carriages are apt to swing. He mentioned that the best coupling was that of Mr. Henry Booth, the talented manager of the Liverpool and Manchester Railway from its very first origin. But, as a general form of combining the draw-boys and buffers on a central rod or tube with spiral springs acting solely from the centre, Mr. Vignoles spoke in the strongest terms of the apparatus of Mr. Thomas F. Bergin, the manager of the Dublin and Kingstown Railway, on which line they had been used with advantage for a number of years.

LECTURE IX.—ON TUNNELS.

In proceeding to treat of the subject, which might be termed that of the great works of art, to be introduced in the formation of roads or canals, but particularly of railways, Mr. Vignoles said that it would not be possible in the lecture-room to go into the details of the constructions, but that he must limit himself to general principles. The rules for consideration when such works ought to be adopted were sufficiently simple; for example, to determine where tunnels should be substituted for open cuttings, or viaducts for embankments. The French engineers, who are in general very much better mathematicians than we are, and probably, from that very circumstance, more inclined to be theoretical, are much in the habit of introducing formulæ which, often very useful, are not always readily applied by the practical men of this country. Supposing it to be required to determine at what point on a longitudinal section (for road, railway, or canal) it is advisable to begin to tunnel, instead of continuing a simple excavation—that is, the point where it becomes as cheap to tunnel as to cut open—for such a case the following formula is given by an eminent French engineer:—Let x = depth of cutting; l = breadth of road, railway, or canal, on the travelling surface; a = depth of bed, of road, or railway, to be first excavated, and afterwards filled with road material or ballast; or depth of canal below the water-line; $\frac{x}{m}$ = slope of excavation; p = price of the cutting per cubic yard. The expense of excavation per yard forward of the sectional area of any cutting will consequently be $a p \times p$ ($l \times \frac{x}{m} = x$; and, when this price exceeds the price per lineal yard forward of tunnelling, the latter is cheaper, supposing the given prices to cover all risk and contingencies in each case. But, as circumstances are continually varying, the English engineer so repeatedly finds that he has to modify—and perhaps finally abandon—the general theoretical rule, and fall back on his own experience, and that of the contractor he may be disposed to employ, that, although he may occasionally resort to such a formula as an approximation, he ceases to employ it in practice, and obtains the sectional area of the given cutting in superficial yards, by simple mensuration, and multiplies it by the price. All the complex conditions involved by slips, faults, water, and the numerous incidental

occurrences in great works, to occasion unforeseen expenses, render prices uncertain, and prevent any fixed general rule; and it is only when the materials and probable contingencies are perfectly well known, that the element of cost can be safely introduced into the mathematical formula. For dry indurated sands, gravel, sandstone rocks, &c., calculations may be made within probable limits of error; whereas, in many instances where the theoretical rule and general opinion, even of those sufficiently experienced, would recommend tunnelling, it has been tried in vain, abandoned after great expense in contending with water, and recourse had after all to open cutting. The average cost of tunnelling upon the principal railway lines, as actually executed, appears to be about 60*l.* per yard forward, in some instances as much as 100*l.*, especially when driven forward in reckless haste, and in attempting to sink shafts or drive drifts, without due consideration as to the quantities of water in the various strata, or the means of at once grappling with the difficulties of drainage or pumping. With great facilities, favourable material, and not too much hurrying, the same area of tunnel has been driven for so little as 20*l.* per yard forward. In round numbers, and on an average, the sectional area of the ordinary tunnel for a double line of railway, to be worked by locomotive engines, may be called 50 superficial yards when finished, or within the ring of brickwork or masonry, if lining were required; in this latter case, the sectional area of the opening to be excavated may be assumed as about 80 superficial yards. Mr. Vignoles observed that, for future tunnel operations, with the benefit of past errors and experience, by avoiding undue haste in execution, and with sufficient caution and activity, 40*l.* per yard forward for tunnelling may be taken as an average approximate fair price. Now if it were wished to compare this expense of tunnelling with the cost of open cutting, the Professor observed that, from his experience, which had been very considerable, in removing earth in large quantities, he was not disposed to put a less price than that of 1*s.* per cubic yard for removing material for deep excavations, especially when this price is to cover contingencies of slips, &c.; with such a price, then, an open cutting 55 ft. deep, roadway 24 ft. wide, and soil requiring slopes of two horizontal to one perpendicular, would give a sectional area of 800 yards—that is, the expense (in estimate) would be the same as that of tunnelling. But Mr. Vignoles observed that, in addition, the future maintenance of the tunnel should be taken into consideration, as well as whether the material from the cutting could be disposed of with advantage; the nature of the soil, and a variety of other circumstances which he stated, all of which would influence the decision. In soft rock, which would work with facility, and yet stand nearly perpendicular, the depth might be very much greater than 55 ft. before tunnelling would be cheaper. In such cases, a depth of 80 ft. and upwards had been resorted to. In chalk the proper slope to be given, which was very variable, would greatly alter any elements of calculation, while, on the other hand, in forming tunnels through chalk, experience had shown that water was the great enemy, and had entailed enormous expenses. The Professor went into a great many other points for comparing excavations with tunnelling, but they appeared too technical to be satisfactorily explained in a brief abstract such as this.

ON VIADUCTS AND AQUEDUCTS.—Mr. Vignoles next proceeded to the consideration of viaducts and aqueducts, into which, he observed, a totally different set of conditions enter, the cost varying from 20*l.* per lineal yard to the price for which no rule could possibly be laid down. Viaducts such as that of which the London and Greenwich Railway wholly consists, may, probably, be executed for 20*l.* to 30*l.* per yard, including the foundations. Of course, the foundation entered materially into the calculation, and where water had to be crossed, largely increased the expense. In some peculiar instances, a large river viaduct, or bridge, has cost as much as 200*l.* per lineal yard. The Professor instanced a viaduct he had built over the river Ribble, at Preston, for the North Union Railway. The length was 300 yards, the height about 45 feet above the water, and the whole mass, including concrete foundations (where the rock was not attained), comprised about 25,000 cubic yards; coffer-dams were used for the piers, and for one abutment. The bridge consisted of five arches, each of 120 feet span, batining on the face and spandrels from the parapet to the impost course—roadway about 27 feet wide; the total cost, including all contingencies, was £45,000, which is 150*l.* per yard forward, or 36*s.* per cubic yard on the whole solid contents; this might be considered a low price, inasmuch as an ordinary brick bridge, of twenty to thirty feet span only, and with facilities for construction, can seldom be built for less than 20*s.* per cubic yard. Where no water or expensive foundations are to be encountered, and where the spans of the brick or stone arches do not exceed about 60 or 70 feet, 1*s.* per cubic foot on the solid contents of the viaducts may be put as a good covering price. Mr. Vignoles stated that, for such viaducts, about 60*l.* to 70*l.* per lineal yard might probably be taken as the average approximate cost, and the additional expense, from a considerable increase of height, does not become so very great, as it chiefly affects the piers only. The Professor then enlarged much on adopting timber arches, with piers of masonry, for viaducts of large span and great height, and produced a number of drawings of such bridges, some actually con-

structed, and some only proposed. The heights were from 70 to 130 ft., the minimum price being 35*l.*, and the maximum 80*l.* per lineal yard. He further pointed out that high embankments should be avoided, and timber viaducts substituted, as a mere point of economy, even without taking into consideration the risk and danger of slipping in such great masses of earth. In an embankment only 40 ft. high, an occupation bridge for a farm would often cost nearly £1000; it was, therefore, only in crossing a very narrow valley or ravine, where no bridges under would be called for, and no masonry—except perhaps a culvert of the very smallest dimensions—that very high embankments should be made. Mr. Vignoles alluded to several such, varying from 70 to 90 ft. high, which he had made, and pointed out a terrible failure in one case, although in other instances success had followed. In passing through hilly countries and along mountain sides torn by ravines, the introduction of the timber-top viaduct, with stone piers, to overcome points of great but partial difficulty, was strongly recommended, especially as great additional height of viaduct could be given at small expense, and thus excavations on each side saved.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ACADEMY OF SCIENCES.

May 30.—The reading of papers connected with the accident on the Versailles Railway occupied a great portion of this sitting. One of the most interesting was by M. François, an engineer of mines, on the means of preventing the crystallization of iron used in machinery. On the examination of the ruptured axle of the engine, which was the cause of the calamity on the 8th ult., the conclusion came to was, that the rupture had been caused by this crystallization, the iron being of the best quality, and of a volume more than sufficient for the purpose to which it was applied. Similar results on other railways have been ascribed to the same cause; but no person has been successful in the means of preventing the recurrence of accident by an improved mode of manufacturing the iron, and all that could be done in the way of precaution was, not to permit iron axles to remain in use for so long a period as to undergo the crystalline change which is so fatal, and of which external appearances give no indication. M. François informs us, that, in a long continued series of experiments, he has observed that a magnetic action upon iron when in a state of fusion, will produce the change alluded to, causing the small and closely adhering grains to crystallize into coarse and larger grains, depriving it of its compact character; and it is inferred that the action of heat upon axles employed in machines, subjected to great velocity, will produce the same effect. This can only be prevented by diminishing the volume of silicate in the iron, by carefully sweating the coal employed in melting, and above all, by the use, in the manufacture of axles, of iron which has already undergone a partial change in its vitreous character, and which, on being reworked, is much less susceptible of crystalline change than new iron. Another communication on the same subject, by Colonel Aubert, was also read. He agrees with M. François as to the cause of the imperfection complained of, but appears to think that the only real precaution is, to change the axles employed in railway locomotives so frequently as not to give time for them to undergo the crystalline change, which is found to be so destructive. Another paper, by Mr. Manby, on the causes of railway accidents, and the means of preventing them, excited much attention. This engineer recommends the use of four-wheeled locomotives, but with some important modifications in the construction of them, both as regards the axles, so as to expose them to an inferior degree of stress than upon the present system, and the frame-work of the wheels, which should, he says, be within the wheels, and immediately under the boilers. He also lays down some practical rules for counteracting the liability of locomotives to run off the rails, and mentions several facts in support of the correctness of the various portions of his system.

A paper, by M. Pambour, on the means of checking, or rather equalizing the velocity on railways, by the use of fans, deriving a force of resistance in the precise proportion of the velocity communicated by the impetus of a train, was next read.

M. Fleurian de Bellevue made a communication on the deterioration of stone in buildings, which he ascribes to an emanation of acid gas from the earth. He recommends a series of minute, but apparently almost impracticable, chemical experiments in the way of analysis of this emanation.

A communication was read from M. Agassiz, announcing that the King of Prussia has placed at his disposal a sufficient sum of money for him to test, in the glaciers of Aar, the truth of his theory respecting the progressive motion of glaciers towards the adjoining valleys. He is about to pierce an opening downwards from the highest point of the glaciers, and expresses a conviction that the result will prove his theory to be correct.

M. Arago addressed the Academy at some length on the eclipse of the sun, then about to take place.

June 6.—A paper *On the nature of the air which we breathe, under various circumstances*, was read. The author, M. Leblanc, has directed his attention principally to an analysis of the air in rooms, hospitals, &c.,—in fact, in all situations wherever it is vitiated by the congregation of persons. He begins by showing, that the air of an empty room, the doors and windows of which are not closed, is precisely the same as that out of doors. This is, of course, natural; but he states also that he found the same to be the case in the closed green-houses of the Jardin des Plantes, a seeming contradiction, which he explains by the absorption by the plants contained in them of the carbonic acid of the air, and the giving out again of this air purified by the plants which had absorbed it. But in one of the wards of the hospital of La Pitié, the doors and windows having been closed, the quantity of carbonic gas—that destructive element to human life—was found to be tripled, as compared with what it was before the room was closed, and, in one of the sleeping-rooms of the Salpêtrière, the quantity of carbonic acid in the morning, the doors and windows having been closed during the night, was eight times greater than in the open air. In the great lecture-room of the Sorbonne, after a lecture of an hour and a half, one per cent. of oxygen had disappeared, and been replaced by one of carbonic acid. The quantity of carbonic acid in one of the écoles d'asile, of Paris, after it had been closed for three hours, whilst the pupils were taking their lessons, was found to be precisely the same as in the experiment at the Salpêtrière. At the Chamber of Deputies, he found the quantity of carbonic acid vary from two to four parts in a thousand. The latter amount approaches the limit at which respiration becomes oppressive and injurious. In the latter portion of M. Leblanc's paper, he gives an account of some experiments with air deteriorated by the burning of charcoal.

INSTITUTION OF CIVIL ENGINEERS.

March 22.—JOSHUA FIELD, V.P., in the Chair.

ON WATER POWER.

"Remarks on Machines recipient of Water Power; more particularly the Turbine of Fourneyron." By Professor Gordon (Glasgow).

NOTWITHSTANDING the diminished importance of water power since the almost universal application of the steam engine, some situations may still be found, in the mining districts of Cornwall, of Derbyshire, and of Cumberland, the Highlands of Scotland, and generally in the districts comparatively destitute of cheap fuel, where it is desirable to render falls of water available.

The theory of water power, as it now stands, may be announced in general terms thus: "The mechanical effect obtained is equal to that of the moving power employed, minus the half of the *vis viva* which the water loses on entering the machine, and minus the half of the *vis viva* which the water possesses when it quits the machine."

Bernoulli recognized the second cause, and soon after Euler the first. Borda, in his "Mémoire sur les Roues Hydrauliques" in 1767, gave the proposition in precise and general terms; whence he concluded that to produce its total mechanical effect, "the water serving as moving power must be brought on to the wheel with impulse, and quit it without velocity."

This principle being admitted, the circumstances next to be considered are: The height of fall—the supply of water—and the nature of the work to be done.

These positions being laid down, the author proceeds to examine the relative efficiency of water wheels of various constructions.

The undershot wheel acted upon by the velocity of the water when confined in a rectilinear course, or when hung freely in a stream: in the former case the efficiency of the machine is equal to 32 per cent. or nearly one-third; in the latter the ratio is 42 per cent. or about $\frac{2}{3}$ ths.

The breast wheel is generally applied to falls of from 4 to 8 ft.; in these the efficiency reaches as high as 60 to 65 per cent. of the mechanical effect of the fall of water. The buckets being filled to two-thirds of their capacity their velocity is seldom less than from 7 to 9 ft. per second.

The consideration of this wheel led Poncelet in 1824-25 to the invention of the "undershot wheel with curved floats," the efficiency of which has been found equal to from 65 to 75 per cent. The velocity of this may be 55 to 60 of that of the effluent water—a velocity equal to that due to nearly the whole height of fall; hence the efficiency becomes "about double that of the ordinary undershot wheel." This wheel has not been much employed in Great Britain, although frequently used in France and Germany.

The overshot wheel is most generally employed in Great Britain for falls beyond 10 ft. in height, and some excellent examples occur for work of every description, from rolling iron to spinning silk. Its efficiency averages 66 per cent. but has risen as high as 82 per cent.

The economical use of water as a moving power varying in particular cases, rendered desirable the discovery of a receiver capable of general application, in all circumstances of height of fall, quantity of water, and amount of work to be done; and after intense study Fourneyron produced the Turbine, the peculiarities of which form the subject of the paper.

The imperfect horizontal water-wheels which have been used for centuries in the mountain districts of central Europe and in the northern Highlands.

are mentioned; then are noticed the experiments of MM. Tardy and Piobert, and the allusion by Borda to horizontal wheels; then a general description is given of the numerous experiments made up to the year 1825, when M. Burdin constructed wheels in which the water was received at the circumference of a vertical cylinder, descended in conduits, placed in a helical form round the surface of the cylinder, and made its escape at the bottom: the efficiency of these wheels was stated to be 75 per cent., but no exact experiments were ever instituted.

The defects in all the previous machines led to the invention of the Turbine as it is now designed by M. Fourneyron: its construction may be compared to one of Poncelet's wheels with curved buckets, laid on its side, the water being made to enter from the interior of the wheel, flowing along the buckets, and escaping at the outer circumference; centrifugal force here becomes a substitute for the force of gravity.

The mechanical construction of the Turbine is then given, and its action is thus described. The water when admitted to the reservoir rises to a certain level, exercising a hydrostatic pressure proportional to the height of the column, and on the sluice being raised it escapes with a corresponding velocity in the direction of the tangent to the last element of the guide curves, which is a tangent to the first element of the curved buckets; the water pressing without shock upon the buckets at every point of the inner periphery, causes the wheel to revolve, then passes along the buckets, and escapes at every point of the outer periphery; by which arrangement the size of the machine even for a large expenditure of water is kept within narrow limits.

The advantages of the Turbines are stated to be—

1st. That they are with like advantage applicable to every height of fall, expending quantities of water proportional to the square root of the fall, their angular velocities being likewise proportional to these square roots.

2nd. That their net efficiency is from 70 to 75 per cent.

3rd. That they may work at velocities much above or below that corresponding to the maximum of useful effect, the useful effect varying very little from the maximum nevertheless, and—

4th. They work at considerable depths under water, the relation of the useful effect produced to the total mechanical effect expended not being thereby notably diminished.

These advantages are stated to have been realized in the extensive practice of M. Fourneyron, of M. Brendel in Saxony, and of Herr Carlitzek in Silesia, as well as other engineers.

A comparison of the theory and practice of the construction is then instituted, and the following conclusion is drawn:—That if one Turbine has been constructed which works well under a known fall, expending a volume of water exactly measured, this Turbine would serve as a type for all others.

Knowing the fall and the volume of water to be expended, the Turbine would be made similar to its type. Its linear dimensions would be those of the type, directly as the square roots of the volume of water, and inversely as the fourth roots of the heights of fall. Its angular velocity would be to that of the type, directly as the fourth roots of the cubes of the heights of fall, and inversely as the square roots of the volumes of water. These practical rules were first made manifest by M. Combe of the Ecole des Mines.

A general review is then given of most of the Turbines erected by M. Fourneyron at Pont sur l'Ognon, at Fraisans, at Niederbronne, and at Inval, upon which last were tried the experiments which completely established the reputation of the Turbine as an applicable machine. The details of these experiments are given, whence the mean results appear to be, that the height of fall being 6 ft. 6 in.—

With an expenditure of 35 cubic ft. of water per second, the efficiency was—

"	63	"	= 0.71
"	79	" (for which it was constructed)	= 0.75
"	126	"	= 0.87
"	144	"	= 0.80

These experiments were tried by the application of Prony's Brake Dynamometer, to the vertical shaft of the Turbine itself.

M. Arago's proposition for employing the power of one branch of the river Seine upon Turbines, to replace the wheels at the Pont Notre Dame, thus giving about 2000 horse power for supplying Paris with water, is then mentioned, as also the results of experiments with very low falls; showing that

With a fall of 3 ft. 9 in. the efficiency of the Turbine was = 0.71

" 2 ft. " = 0.64

" 10 in. " = 0.38

The Turbines of Mülbach and Moussay are mentioned, as are the failures of several of these machines constructed by other engineers, and the paper concludes with an account of a Turbine at St. Blazeux in the Black Forest, where the height of the fall is 345 ft., the quantity of water 1 cubic foot per second, and the reported efficiency from 80 to 85 per cent.*

Remarks.—Mr. Taylor said that Professor Gordon's Paper on the Turbine had been brought before the Institution with the advantages of illustration afforded by the model made under the superintendence of Mr. Jordan for the Museum of Economic Geology; a most useful institution, for the present advanced state of which the country is in a great degree indebted to the

* The discussion upon Professor Gordon's, and Professor Moseley's Papers extended over several evenings, but are all recorded together for the sake of facility of reference.

zeal and scientific knowledge of Mr. De la Bèche, who conducts the geological survey of the kingdom ordered by the Board of Ordnance.

The Institution was indebted to the courtesy of Mr. De la Bèche for the exhibition of the model, and Mr. Taylor had been anxious that the subject should be brought forward at this time, as the only period at which such a permission could have been granted; for models once deposited in the museum were not allowed to be removed. But it had been arrested in its passage from the hands of its maker, and thus had been procured for the inspection of members of the Institution.

Mr. Taylor then proceeded to remark, that, although the improvements in the application of steam had rendered water power of less value than formerly, yet there were many situations, particularly in the mining and high-land districts, where it was still employed beneficially. And as an instance of the extent to which water power might be applied, he mentioned a case in Devonshire, where in the adjoining mines of Wheal Betsey and Wheal Friendship, near Tavistock, which have for many years been under his management, a fall of water of 526 ft. in height is employed in giving motion to seventeen overshot wheels, eight of them performing the duties of pumping water from a depth of nearly 200 fathoms. The diameter of the largest of these wheels being 51 ft. with a width of breast of 10 ft. clear within the rings, the smallest of the eight being 32 ft. diameter, and the others of intermediate sizes.

Four other wheels give motion to machines for drawing up the ores to the surface, their diameters varying from 40 to 26 ft.; and the five remaining wheels are employed for mills for crushing and stamping the ores. In addition to all this power, a steam-engine with a cylinder of 80 in. diameter, and 10 ft. stroke, is provided as an auxiliary in periods of drought or frost.

He then gave the distribution of this water power in the following tabular form:—

OVERSHOT WATER WHEELS employed in pumping water at Wheal Friendship Lead and Copper Mines, near Tavistock, in July, 1841. From data furnished by Mr. Anthony Rouse, engineer at those mines.

All the wheels operate on their pumps by means of a simple crank formed on each end of the centre axis or gudgeon, on which the wheel is mounted. Two long rods extend nearly in a horizontal direction, from the pins of those cranks, to the upright arms of two bell-crank or elbow levers, which are situated at the mouth of the pit, or shaft, and from the horizontal arms of those elbow levers, two vertical pump-rods are suspended, in the pit. Those rods and the pump-work are the same as commonly used for steam engines in Cornwall, with plunger pumps, except that there are two pump-rods in each pit, and they move up and down in contrary directions, owing to the two cranks on the ends of the axis of the water-wheel being bended in opposite directions; by that arrangement the weight of the two rods counter-balance one another; one half of the pumps are connected to one rod, and the other half to the other rod, and the water is raised in the pumps by turns. All the wheels have a considerable length of horizontal rods, to extend from their cranks to the elbow or bell-crank levers at the pit's mouth; and in some cases a very considerable length of such rods, occasioning much friction.

1. *Old Sump Wheel*, 51 feet in diameter, 10 feet broad. The water poured into its buckets was at the rate of 5632 gallons per minute; which, at 10 lb. per gallon, would be 56,320 lb. weight, descending 51 feet = 2,872,320 lb. per minute descending 1 foot; that is, the power of the water expended; or being divided by 33,000 lb. (for a horse power according to Mr. Watt) gives 87.0 horse power expended.

The wheel when so supplied made 5 revolutions per minute, and worked 6 pumps, as follows:—

Lifts.	Fath. Feet.	Diam.	Weight.
			lb.
1	43 1½	13½	16,136
3	112 3½	13	38,922
1	25 3	14	10,225
1	6 5	9	1,132
			66,415

The length of stroke in the pumps was 6 feet; and the effective motion in the pumps to raise water, was at the rate of 30 feet per minute.

The weight of the columns of water in all the 6 pumps, amounted to 66,415 lb. weight, which being raised 30 feet per minute = 1,992,450 lb. per minute raised 1 foot; that is, the power realized or exerted in actually raising the water; or being divided by 33,000 gives 60.36 horse power realized.

Wherefore an expenditure of water power equal to 2,872,320 lb. per minute descending 1 foot (or 87.0 H.P.) produced a useful effect realized in water raised by the pumps, equal to 1,992,450 lb. per minute raised 1 foot (or 60.36 H.P.); the useful effect or work done being at the rate of 69.4 per cent. of the power expended, the remaining 30.6 per cent. being lost, partly by friction of the pump-work, and resistance to the motion of the water

through the pumps, and partly by imperfect application of the water to the wheel.

II. *Taylor's North Wheel*, 50 feet diameter, $6\frac{1}{2}$ feet broad; was supplied with 5199 gallons of water per minute=78.75 h.p. expended. It made 5 revolutions per minute, and worked 6 pumps with a stroke of 6 feet; weight of the columns of water in those pumps 44,689 lbs., which was raised 30 ft. per minute=40.63 h.p. realized; being 51.6 per cent. of the power expended.

III. *Taylor's South Wheel*, 40 feet diam. $4\frac{1}{2}$ feet broad; supplied with 4167.4 gallons=50.5 h.p. expended. It worked 2 pumps, 6 feet stroke, 5 strokes per minute; weight of columns 30.270 lb.=27.53 h.p. realized; being 54.5 per cent.

IV. *Brenton's Wheel*, 32 feet diam. $7\frac{1}{2}$ feet broad; supplied with 8897.4 gallons=86.3 h.p. expended. It worked 5 pumps, 6 feet stroke, $4\frac{1}{2}$ strokes per minute; weight of column 30.092 lb.=24.63 h.p. realized; being only 28.5 per cent. of the power expended, which is to be accounted for by the additional friction of a great length of horizontal rods by which this wheel works its pumps.

OVERSHOT WATER WHEELS AT WHEAL BETSY MINES, IN JULY, 1841.

I. *Job's Wheel*, 42 feet diam., supplied with 2890 gallons of water per minute=36.78 h.p. expended. It made 4 revolutions per minute. Weight of the columns of water in the pumps 28.314 lb. 6 feet stroke=20.6 h.p. realized; being 56 per cent.

II. *Williams's Wheel*, 40 feet diam.; 3027 gallons per minute=36.68 h.p. expended. It made $4\frac{1}{2}$ revolutions. Weight of columns 26.454 lb.; $7\frac{1}{2}$ feet stroke=26.45 h.p. realized; being 72.1 per cent.

III. *Buller's Wheel*, 40 feet diam., 1912 gallons=23.17 h.p. expended. It made 3 revolutions. Weight of columns 22.901 lb. $7\frac{1}{2}$ feet stroke=15.61 h.p. realized; being 67.4 per cent.

IV. *Carpenter's Wheel*, 44 feet diam., 1985 gallons=26.46 h.p. expended. It made $4\frac{1}{2}$ revolutions. Weight of columns 18.662 lb., 6 feet stroke=15.26 h.p. realized; being 57.6 per cent.

Conclusion.—If Brenton's Wheel at Wheal Friendship is rejected, as an extreme case, the average performance of the other three wheels at Wheal Friendship will be 58.5 per cent.; and of the four wheels at Wheal Betsy 63.3 per cent. Or the average performance of all the seven wheels will be 61.2 per cent.

Wheal Friendship.	Old Sump	69.4	} 58.5 per cent.
	Taylor's North	51.6	
	Taylor's South	54.5	
	Job's	56.0

	Buller's	67.4	
	Carpenter's	57.6	

Mr. Jordan described the turbine to consist of three principal parts:—

1st. A cylinder with a base upon which are fixed the guide curves, directing the water at a certain angle upon the buckets of the moving ring.

2nd. A sluice regulating the flow of water from the bottom of the cylinder upon the buckets, and

3rd. The external or revolving ring with its buckets, and its upright shaft whence the motion is communicated to the machinery to be driven.

The buckets are confined between two annular plates, the lower one being attached to the vertical shaft, in the bottom of which is fitted a hardened steel thimble, into which a pivot of "glass-hard steel" works; this inversion of the ordinary arrangement of the pivot, is to prevent any particles of sand or other substances from getting upon the point, and producing friction. Oil is introduced to this pivot by a tube connected with a small pump, worked by the machinery at the requisite speed to keep it lubricated.

The form of the buckets is a mathematical curve, and on the perfection with which this is traced, will depend the efficiency of the turbine.

These parts are enclosed within a cylinder, so arranged that it shall serve as the reservoir, whence the water is admitted upon the moving parts by the sluice, which must be well fitted to prevent a loss of water, and is uniformly raised or lowered by gearing placed on the top of the cylinder. When the height of the fall is considerable, the cylinder is closely covered, and the moving shaft passes through a stuffing box in the centre, but with low falls the cylinder is open at the top.

A great advantage in the machine is, that the castings and iron work composing it, are (with the exception of the buckets) very simple, they require little adjustment, and only a few parts are turned or bored, so that the construction ought to be economical.

Mr. Rennie had endeavoured to introduce the turbine into notice some years ago, and the nature of the curves had been examined in an article in *Herapath's Magazine*. Professor Gordon's statement corresponded very nearly with what he had heard from MM. Fourneyron, Arago and Morin, and subsequently seen of these machines when in France. He had visited a turbine erected by a Mr. Isterwood at a flour-mill at St. Maur, near Paris; the machine drove ten pairs of millstones 3 feet 4 inches in diameter, at the rate of 200 revolutions per minute, equalling 40 h.p.; subsequently three additional turbines were erected for the purpose of driving ten pairs of stones each, or in all forty pairs of stones by four machines; each turbine had a diameter of 5 ft. 2 in. and a depth of bucket of 8 inches, with a fall of water of about 6 ft.: when entirely submerged to the depth of 4 feet, the turbine

continued to make (as in low water) 50 revolutions per minute. Subsequently, in September 1840, he visited the flour mills of M. D'Arblay at Corbeil. These mills are four in number arranged in a quadrangular form; each mill contains ten pairs of millstones, which were originally driven by four well-proportioned cast iron wheels of about 18 ft. diameter; two out of the four wheels were still at work, but the other two had been replaced by two turbines similar in dimensions to those at St. Maur. One of them was working ten pairs of stones. The motion was communicated to a horizontal shaft by means of bevil wheels, one fixed on the upper extremity of the upright spindle of the turbine, the other of smaller diameter fixed on the end of the horizontal shaft, on which also were fixed the riggers for driving, by means of straps, smaller riggers fixed on the millstone spindles. The work was very regularly done, and the proprietors expressed great satisfaction. The second turbine was then erecting, and the third and fourth water-wheels were to be replaced by similar machines. No fault was attributed to the original wheels, but their effect was not equal to that of the turbines. The *ouaker* (Mr. Isterwood) stated that he had made these machines entirely under the direction of M. Fourneyron, who alone knew how to trace the directing and emissive curves, and that unless they were properly described, the effect would be greatly reduced. He at the same time stated as his opinion, that there was no economy in the construction of the turbine over the common water-wheel, as the former is more complicated and costly. M. Fourneyron seemed to doubt whether any other machinist than himself could construct a turbine properly; the principal difficulty being in tracing the curve, which had been the study of his life; he quoted several instances of failure when strangers had attempted their construction. M. Arago and M. Poncelet were of the same opinion; the former stated that the effect of the curves was contrary to theory. M. Morin expressed his confidence in the accuracy of the experiment made with the *frène* or friction brake of Prony applied to the axes of the turbines.

Mr. Rennie had seen a cast iron water-wheel with close buckets very nicely balanced, 24 ft. diameter and 5 ft. 6 in. wide, made under the direction of his father, realize 80 per cent. of effective power, and Professor Gordon in the paper spoke of 82 per cent. for an overshot water-wheel. He did not however by these observations mean to disparage the turbine, with which the mechanical world generally was not sufficiently acquainted.

Mr. Taylor thought that Mr. Rennie had overlooked the two prominent advantages of the turbine, in comparing it with other methods of employing water power.

1st. That of its being equally adapted for very low or for very high falls; in falls under 10 feet the breast-wheel afforded but an imperfect mode of using the power, as the actual efficiency fell far below what ought to be obtained by a more perfect machine; and in falls above 50 or 60 feet, if overshot wheels were used, a number of them must be constructed with the disadvantage of increased expense and probable inconvenience in their application. Instances had been adduced of turbines working with a fall as low as 2 feet and as high as 345 feet; the efficiency of the former being stated at 64 per cent. and of the latter from 80 to 85 per cent.

2nd. That they are not affected by back or tail water like almost all other hydraulic machines; it having been shown, by direct experiment, that when working at considerable depths under water, the relative proportion of useful effect produced, to the total mechanical effect expended, is not thereby notably diminished. This in his opinion was one of the most important advantages of the turbine.

For high falls, the water-pressure engine and Barker's mill, as improved by Whitelaw and Stirratt, rivalled the turbine; and for low falls there were many machines which were very effective; for instance the balance-engine, and the old "flap-jack," with a reservoir of water at one end of a beam and a pump at the other; he had seen such a machine working with a ten-foot stroke, pumping from a depth of 200 fathoms: but for falls subject to great fluctuation, none of these machines appeared to equal the accounts given of the turbine.

Mr. Farey had not collected from the paper, or the discussion, how the quantity of water passing through the turbine had been measured. The power exerted appeared to have been tried by a break applied directly to the axis of the turbine, whereas ordinary water-wheels are usually tried by the work which they actually do perform, and that by the intervention of machinery which causes a considerable loss of power by friction. In order to make a fair comparison, the two kinds of machines should have been experimented upon exactly in the same manner, which did not appear to have been done.

When Mr. John Taylor stated, that the effect of the best of the large water-wheels used for pumping water out of the mines under his management, had been calculated to be 69 per cent. of the power expended; it would be found that the effect produced had been computed by the weight of the columns of water in the pumps, multiplied by the height through which such weight was raised; such being the usual mode of reckoning. But it is obvious, that much more power was exerted by the water-wheel than would thereby be brought to account in the 69 per cent., owing to the friction of the pit-work and pumps by which the water was raised. The turbines appear to have been tried in a way which would not incur much of that loss, but which would bring to account in the per-centage nearly all the power which, in practical operations, must be lost by the friction of the machinery with which a water-wheel or a turbine must of necessity be connected, in order to perform such operations.

PROFESSOR MOSELEY'S CONSTANT INDICATOR.

"Results of a Trial of the Constant Indicator upon the Cornish Engine at the East London Water-works." By Professor Moseley, F.R.S., &c.

The object of this communication is to exhibit and explain the results given by the author's Indicator during a continuous registration from the 28th January to the 25th February, 1842, the engine during that time making 232,617 strokes. The numbers registered by the counter of the engine and the Indicator were noted each morning and evening, and are recorded in a table appended to the paper. The differences between each two consecutive numbers registered by the counter, giving the number of strokes made between each two observations, are contained in one column of the table, and in another column are the differences between the successive registrations of the Indicator. These are followed by the mean registrations of the Indicator at every stroke of the engine, being the quotients of the numbers in the last-named column divided by the corresponding numbers of the preceding column. The paper, after thus stating the numbers registered daily by the Indicator during the period of trial, proceeds to explain the formula to which they are to be applied, in order to determine the work done daily by the engine. The formula, when reduced from the general one by the introduction of the numerical values of the constant dependant upon this engine, is

$$U = 161.4474 N - 0.9051 L.$$

In this expression, U represents the units of work (in lb. raised one foot high.) done upon each square inch of the piston through any given time, during which the number registered by the Indicator is represented by N, and the space in feet which the piston traverses, by L. The second term of the formula, which is very small as compared with the first, is a correction for the influence of the friction of the Indicator on the number registered by it. The formula being then reduced by the substitution in it of the numerical values before alluded to, the whole number of units of work per square inch of the piston done between the 28th January and the 25th February is shown to have been 21,464,067.1727. From this is deduced the work done during the same time upon the whole area of the piston as well as the duty done upon the piston for each cwt. of coals. These calculations are followed by a comparison of the results given by the Indicator with those previously obtained from actual experiment by Mr. Wicksteed; whence it appears, that with a necessary allowance for a difference in the lengths of stroke at the periods of the two experiments the results of the two are almost coincident. The work per stroke upon every square inch of the piston as obtained by experiment is 120.574, whilst as shown by the Indicator it is 119.336 lb.

Professor Moseley exhibited the Indicator, and described its construction and action;* the accompanying engraving (Plate XI.) represents the Indicator constructed by the committee. C and D are cylinders, each four inches in length, communicating by the steam steam-pipes A and B with the top and bottom of the cylinder of the engine to which the Indicator is applied, and well clothed with felt to prevent radiation. In these cylinders work two solid pistons, each four square inches in area, fixed upon the extremities of the same piston-rod E F, which piston-rod (when the steam passages A and B are open and the Indicator is in action) sustains in the direction of its length a pressure equal to the difference between the pressures upon the two pistons fixed upon its extremities, or (since these sustain the same pressure with equal portions of the opposite sides of the piston of the engine) equal to the effective pressure of the steam on four square inches of the piston of the engine. This pressure upon the piston-rod is made to bear, by means of a shoulder Z, upon the steel spring S T, which spring is connected by means of links at its extremities with a second similar and equal spring Q R, supported at its centre upon a solid projection P, from the cast-iron frame of the instrument. The pressure of the piston-rod upon the lower spring borne at the extremities of the upper spring, whose centre is fixed, is thus made to separate the two springs from one another, and the separation produced is, by a well-known law of deflection, directly proportional to the pressure sustained, so long as the deflections are small. The limits within which this law of deflection obtains, are greatly extended by the peculiar form given to these springs, first suggested (it is believed) by M. Morin. One surface of each spring is plane, and the opposite surface of that well-known parabolic form by which an equal strength is given to every portion of the length of the spring. The spring being thus tapered from its centre to its extremities without impairing its strength, its deflection is distributed more uniformly throughout its length, and being thus made less (for a given separation of the springs) at every point, the elastic limits are nowhere so soon passed.

By this connection of the piston-rod with the springs, its position is made to vary directly as the effective pressure upon its extremities, or as the effective pressure upon four square inches of the piston of the engine, so that every additional pound in that pressure will cause the piston-rod to alter its position by the same additional distance in the direction of its length.

The pulley or wheel I K (which, from the peculiar functions assigned to it in this machine, we propose to call the *integrating wheel*.) turns upon the piston-rod as its axis, and traverses with it at the same time in the direction of its length, being prevented from moving on it in that direction by means of two shoulders fixed by adjustment screws.

The arms of this wheel are pierced by apertures, through which pass three rods united at their extremities (as shown in the figure,) so as to form the rigid frame G H, which frame turns also upon the piston-rod as its axis, but does not traverse with it in the direction of its length; so that the wheel I K is made by its motion with the piston-rod to traverse the rods of the frame longitudinally, whilst it is made to sweep the frame round with it by any motion of rotation which may at the same time be communicated to it about its axis. It receives such a motion of rotation from the cone K L, which is so placed that its side may be accurately parallel to the piston-rod, and which is kept continually pressed against the wheel at K by means of a spiral spring enclosed in a tube at M, and acting continually against the extremity of the spindle on which the cone turns.

A system of bevel wheels U, Y, X, communicates to this spindle, and with it to the cone, the rotation of the pulley N, which pulley is driven by a cord carrying a weight at one extremity, and passing by the other extremity (over directing pulleys) to the piston of the engine, or to some point which moves *precisely as the piston of the engine does, but through a less space*. The circumference of the pulley N being thus made to move precisely as the piston of the engine, the angle described by the cone, during any exceedingly small period of time, is made to be exactly proportional to the space described during that time by the piston of the engine. Now let it be observed, that the circumference of the integrating wheel I K partaking of the motion of that portion of the surface of the cone with which it is at any instant in contact, the number of revolutions, or rather parts of a revolution, which it is made to describe during any exceedingly small period of time, beginning from that instant, is dependent upon two causes; first, upon the dimensions of the particular circle of the cone which is at that instant driving it, and, secondly, upon the particular angle through which it is driven by that circle, that is, it depends, first, upon the distance of its point of contact K with the cone from the apex of the cone at that time, and, secondly, upon the angle which the cone describes about its axis during that small period of time. Moreover, that if either of these two elements of variation remained always the same, then the number of revolutions, or parts of a revolution, made by the wheel, would vary directly as the other, whence it follows by a well-known principle of variation, that when (as in the present case) both these elements vary, it varies as their product; or that the number of revolutions, or parts of a revolution, made by the integrating wheel during any exceedingly small period of time, varies directly as the product of two factors, of which one is the angle described during that time by the cone, and the other the distance of the point of contact K of the cone and wheel from the apex of the cone.

Now the former of these factors has been shown to vary directly as the space described during that small period of time by the piston of the engine, and the latter to vary directly as the effective pressure which the steam is then exerting upon the piston of the engine.*

Thus, then, it appears that the number of revolutions, or parts of a revolution, made during any exceedingly small period of time by the integrating wheel, varies as the product of the space described by the piston of the engine during that time, by the effective pressure of the steam upon it during that time, that is, it varies as the *work* or *dynamical effect* of the steam upon the piston during that time. And this being true in respect to every small period of the time during which the stroke of the engine is in progress, is true of the whole stroke; whence it follows, that the number of revolutions, and parts of a revolution, made by the integrating wheel during the stroke is proportional to the whole work, or dynamical effect of the steam upon the piston during the stroke.

The integrating wheel carries round with it the frame G H, on the hollow axis of which frame is fixed a pinion running into a wheel, whose axis turns upon bearings fixed to the frame of the instrument, and the number of whose teeth is to that of the teeth in the pinion as ten to one. This wheel carries also a pinion running into a second wheel, their numbers of teeth being in the same proportion, and so through a train of five wheels and pinions. The circumference of each of the four last wheels is divided into ten equal parts and numbered, and the circumference of the first into 100. The number of revolutions of the integrating wheel is thus registered to five places of integers, and to one place of decimals.

Now this number of revolutions has been shown to be proportional, in respect to each stroke, to the work done by the steam upon the piston during that stroke; if, therefore, the action of the Indicator continued the same during successive strokes, or if the direction of the pressure of the steam upon the piston, and that of the motion of the piston, were not reversed at every stroke, then would the number registered during any number of strokes of the engine be directly proportional to the work done by the steam upon its piston whilst that number was registered. At the return-stroke of the piston of the engine, the pulley N, however, revolves backwards, and supposing it to carry with it the spindle of the cone, the cone also revolves

* The Editor is indebted for the annexed engraving of the apparatus and description to a report of a committee appointed at the tenth meeting of the British Association. Members of the committee, the Rev. Professor Moseley, M.A., F.R.S., Eaton Hodgkinson, Esq., F.R.S., J. Enys, Esq.

* The position of the integrating wheel upon the piston-rod is so adjusted, that before the steam is admitted the integrating wheel may be brought, by the elasticity of the springs, exactly to the apex of the cone. In order to prevent it from being stopped by the apex of the cone, if accidentally it should be made to pass it, a solid piece projects from the frame of the instrument, having its surfaces adjusted so as to receive the edge of the wheel when it is forced beyond the apex of the cone, and to serve as a stop to the motion of the cone in the direction of its spindle when the resistance of the wheel is thus removed from it.

PROF^r MOSELEYS CONSTANT INDICATOR FOR STEAM ENGINES.

backwards, so that if the integrating wheel remain in contact with the cone at any other point than its apex, it too will be made to revolve backwards, and the number registered in the preceding stroke will thus be *diminished* by the number of revolutions made by the integrating wheel during this stroke: but let it be observed, that before the motion of the piston of the engine is reversed, the direction of the pressure of the steam upon it, and therefore the direction of the pressure upon the piston-rod of the Indicator is reversed, by which altered direction of the pressure, as well as by the elasticity of the springs, the integrating wheel is made to ascend to the apex of the cone, and to remain there during the return-stroke, so that no number whatever is registered during that stroke.

Thus, then, the remaining number registered during any time by the instrument when applied to the double acting engine, is proportional to the work done upon the piston by the steam at the alternate strokes during that time. The mathematical formula by which the work is determined from this number, and allowance made for the friction of the Indicator, is given in a subsequent part of this report.

In order effectually to guard against any error which might accidentally result from the reversed motion of the piston, a contrivance has been introduced in the combination of wheels Y, X, U, by which the revolution of the cone may be arrested whilst that reversed motion takes place. To adapt the instrument to register (if required) the work done at *every* stroke of the piston, a four-way cock has been constructed, which may be made, by the action of the engine, to control the direction of the steam passages of the Indicator, in such a way that the upper cylinder C shall always communicate with that portion of the cylinder of the engine which is filled with steam, whilst the lower cylinder D is made always to communicate with the vacuum. When the Indicator is thus used, the cone is made, by a simple adjustment of the mechanical combination U X Y, to revolve constantly *forwards*, whilst the motion of the piston of the engine, and therefore of the pulley N, *alternates*. It remains now only to speak of the application of the Indicator to the single acting engine, or Cornish engine.

The registration during the down or in-doors stroke of that engine is already explained. During the first portion of the *up* or out-of-doors stroke the equilibrium valve is opened, and the pressure upon both the pistons of the Indicator thus becoming the same, the integrating wheel is brought by the elasticity of the springs to its initial position at the apex of the cone, and thus, although the cone turns backwards, the wheel remains at rest and nothing is registered. When the equilibrium valve closes, the pressure of the steam in the upper portion of the cylinder of the engine, and therefore in the upper cylinder C of the Indicator, preponderates; the integrating wheel descends from the apex of the cone and the register revolves backwards, deducting from, or diminishing, the number before registered by precisely the number of units of work which is done by the steam (jammed back into the upper portion of the cylinder) *against* the returning piston. Now this is precisely the deduction which the theory of the steam engine shows ought in this case to be made, and the registration of each double stroke of the single acting or Cornish engine is, by this backward movement of the integrating wheel, *perfected*. Let it be here observed, that the Indicator in the *down*-stroke performs the definite integration of a *logarithmic function*, viz. that which represents the pressure of the steam as a function of space, described by the piston during the expansion of the steam, that it then calculates the numerical amount of the integral it has thus completed, and registers that amount; that it performs a similar operation in the *up*-stroke, and deducts the corresponding amount as a correction from the first.

The above must be received as an attempt to place the theory of the instrument under a general and popular form. A mathematical discussion of it accompanies this Report, in which the corrections due to friction and other causes are fully considered.

FORMULÆ FOR DETERMINING THE WORK OF AN ENGINE BY MEANS OF THE INDICATOR.

The following are the values of the constants which enter into the general equation in its application to the Indicator constructed by the Committee.

Radius of the integrating wheel. $\rho = 2.99$ in.
 Radius of the piston of the indicator = $r^* = 1.125$ in.
 Radius of the pulley measuring to the centre of the cord = $R = 3$ in.
 Angle at apex of cone $= 2\epsilon = 90^\circ$
 Friction of piston, of integrating wheel on cone, &c., mean value = $F = 1.2074$ lb.

Additional deflection of springs due to each additional pound of pressure on piston of Indicator = λ Spring No. 1 = .028.
 Substituting the above values of ρ , r , R , ϵ in equations (2) and (3), we obtain for double acting engines,

$$U = 1.67052 \left(\frac{m}{\lambda} \right) N - \frac{1}{2} F \left(1 - \frac{2}{p} \right) L \dots \dots (4.)$$

for single acting Cornish engines,

$$U = 1.67052 \left(\frac{m}{\lambda} \right) N - \frac{1}{2} \left(m \frac{2}{p} + \frac{1}{n} \right) F \cdot L \dots \dots (5.)$$

* The radius of the piston is so taken that its area may equal exactly four square inches.

If in these equations we substitute the values of λ for the different systems of springs, and also the *mean value* of F , which is 1.25 lb., we shall obtain for *spring* No. 1, $\lambda = .028$ in.

$$U = 59.6614 m N - .3018 \left(1 - \frac{2}{p} \right) L \text{ (common engine).}$$

$$U = 59.6614 m N - .3018 \left(1 - \frac{2}{p} + \frac{1}{n} \right) L \text{ (Cornish engine).}$$

The values of U , obtained from the above formulæ, being multiplied by the number of square inches in the surface of the piston of the engine, will give the whole number of units of work yielded by it during the time of the experiment.

It will be observed, that no account is taken in these formulæ of the weight (3 lb. 0½ oz.) of the pistons, the integrating wheel, and the rod to which these are attached. The influence of this weight is, in fact, allowed for when, the springs being placed in the Indicator, and therefore loaded with it, and sustaining no other pressure, the integrating wheel is moved to such a position upon the rod as that its circumference may coincide with the apex of the cone. The springs are then just so much deflected as by their elasticity to sustain this weight, and that initial deflection remaining super-added to any additional deflection to which they may be subjected by the additional strain thrown upon them, the weight of the pistons, &c. will in every position be accurately balanced by it, and the additional strain thrown upon the springs will produce precisely the same deflections as though no such weight existed.

Mr. Moseley then described the difference between the instrument and that of M. Morin for applying the principle of M. Poncelet, to consist—First, in all those mechanical combinations which are peculiar to the instrument in its application to the steam-engine, M. Morin's instrument having been applied to measure the traction of horse.—Secondly, in the surface of a cone being substituted for the plane surface of a circular disc; by which arrangement the rapidity of the changes of velocity due to corresponding changes in the position of the integrating wheel, is diminished in the same proportion in which the sine of one-half the angle of the cone is less than unity; and the force necessary to drive the integrating wheel being diminished in the same proportion, the chance of an error arising from the slipping of the edge of the integrating wheel on the surface from which it receives the impulse is lessened in proportion.—Thirdly, in the separation of the registering apparatus from the integrating wheel; by which separation, whilst the springs are relieved from the effect of the momentum and the friction due to the weight of the registering apparatus, the latter being in a state of quiescence, the registration is legible whilst the Indicator is in action.—Fourthly, in the variable position of the links connecting the springs together, by which variation the same series of deflexions may be obtained under different ranges of pressure. In fact, that the Indicator has nothing in common with the "compteur" of M. Morin except the principle of M. Poncelet and the springs under a modified form.

The amount of the friction of the pistons, was then examined and the peculiar construction of their metallic packing explained; it was shown also that instead of great difficulties arising from the friction of the integrating wheel upon the cone, or its slipping upon the surface, a very slight pressure of the spring produced sufficient adhesion to drive the registering apparatus. The professor then explained the advantages resulting from a registration of the duty of steam-engines generally, not during the time of a few isolated experiments, as with the common Indicator, but extended over any given period and through every stroke of the engine, displaying all the changes which had occurred during that time:—with this view it had been decided that the instrument should be attached to the engines of the Great Western steam-vessel on her next voyage to America.

He then expressed his obligation to Mr. Wicksteed for the facilities afforded him for the experiments at Old Ford, and paid a well-merited compliment to Mr. Holtzapffel for the excellent construction of the Indicator.

Remarks.—In reply to a question from Mr. Vignoles, Mr. Moseley stated that the instrument was not under its present form adapted to locomotive engines, but that a grant of £100 had been made by the British Association for the construction of such an instrument.

Mr. Cowper, in compliance with the request of Professor Moseley, illustrated his description by setting the instrument in motion, showing that the registration depended upon the revolutions of the integrating wheel: he demonstrated the cases of motion without pressure, and pressure without motion; in the former case the integrating wheel being stationary at the apex of the cone while revolving, does not receive any impulse from the contact with it, and therefore does not register; in the latter case, the surface of the cone upon which the integrating wheel traverses, being at rest, does not communicate any rotative motion to it, and consequently no registration can take place; but when motion and pressure are combined, the cone revolving and the integrating wheel travelling from the apex some distance towards its base, the exact product of the motion of the cone and the steam's pressure upon the piston would be registered by the amount of the revolution of the integrating wheel.

Mr. Wicksteed observed that every facility had been afforded to Professor Moseley for applying his new Indicator for the purpose of ascertaining the duty performed by the Cornish engine at Old Ford, but that he had not at all interfered with the experiments, being desirous of ascertaining whether the results would correspond with his trials. That after the work of the

engine had been registered while it was making about 179,000 strokes, the mean result as stated by Professor Moseley was so nearly that arrived at by Mr. Wicksteed, that he had no doubt of the accuracy of the machine as a good indicator of the real duty performed by the engine, the difference in the result of the mean pressure of the steam, deducting the vacuum, or 0.73 lb., was 0.12 lb., namely, according to Mr. Wicksteed's experiments $12.94 - 0.73 = 12.21$ lb., and according to Professor Moseley 12.09 lb.; this difference might arise from a variation in the mean length of stroke during the two sets of experiments—from a slight variation in the point at which the steam had been cut off—from a variation in the level of the water in the pump well, or other practical causes; the difference however was so insignificant, that he would rely on the accuracy of Professor Moseley's Indicator, and allow the possibility of a slight error in his own experiments.

Mr. Farey observed that Professor Moseley's instrument must be influenced by variations in the length of stroke, for whenever the piston makes a long stroke, the cone and the train of registering wheels, must be turned farther round, and would register a higher number than they would do in case of a shorter stroke; supposing the impelling force exerted by the steam to be always the same. If the instrument could be really made to give its results according to the actual length of all the varying strokes made during the time of observation, by truly aggregating these varying lengths into one sum, the results would be free from the usual uncertainty respecting an average length of stroke. In the monthly reports of engines in Cornwall, the performance is reckoned according to some reputed length of stroke, which had been fixed upon for each engine, when it was reported, and it is afterwards assumed that no departure from that reputed length has taken place, when, in fact, such departure does often occur.

It would be very desirable to have a moving card applied to the new instrument, in order to indicate the impelling force of the steam in the cylinder by tracing curves on paper, like those by the ordinary indicators. This it appeared might be done, with the advantage of causing the paper on which the curve is drawn to travel onwards and bring fresh paper into its place, so as to obtain a series of distinct curves for as many succeeding strokes.

The form of the springs of Professor Moseley's instrument would be a decided improvement if substituted for the spiral spring of ordinary indicators; Mr. Farey had applied to an ordinary indicator a mode of exhibiting at a glance, whether the engine was exerting more or less force than its ordinary appointed task; the plan answered that purpose: but as it required the indicator to be always in action, the spring of the indicator broke after working more than two days, he therefore abandoned it. The springs in the new instrument were proved by the trial at Old Ford to be capable of enduring continual exertion without breaking. The professor had stated that the scale of flexure of the new springs was found to be exactly, according to theory, equal divisions with equal forces; this might be expected because the flexure of the springs was small, and the bending force acted in a direction nearly at right angles to the length of the springs. In ordinary indicators the scale should not always be equal divisions, because the wire of the spring being wound spirally into a screw of small diameter, the spiral obliquity of the thread of such screw becomes more oblique to the direction of the bending force, as the spring is stretched, and less oblique as the spring is compressed, and hence the scale of pounds per square inch by which the curve should be measured for summing up the results, ought to be a scale of unequal divisions.

The indicators originally used by Boulton and Watt were of a large size, with a long and powerful spring curled into a cylindric form, as large in diameter as could be included in the cylinder of the indicator, and the motion allowed to the piston by the spring was very short; such indicators were judiciously proportioned, and they do not show any sensible inequality of divisions in their scale. But recently, indicators have been frequently made without the knowledge of their true principle, and the rules of proportion are not observed, so that it will sometimes be found, on actual trial of such instruments with weights, that their scale of pounds per square inch is not in equal divisions, although it is usual to employ a scale of equal divisions for summing up the curves traced by them. In Boulton and Watt's indicators the scale of pounds per square inch was formed from actual trial with weights, but such trials were made when the indicator was cold, and dismounted from its place upon the steam engine. A much better mode is to apply the weights on the upper end of the piston-rod when the indicator is placed on the cylinder of the engine, while it is hot, its piston being supplied with the same quantity of oil, and the spring being in the same state as when it is in use. The depression of the piston by the weights is recorded by drawing a line with the pencil of the instrument on the card itself, in the same manner as the usual atmospheric line is drawn thereon. A series of lines thus drawn with given weights, become so many original stages for subdividing between them, to form a true scale for summing up the curve described under the same circumstances and nearly at the same time.

Professor Moseley's instrument had two cylinders and pistons operating in concert on the same piston-rod, and springs of peculiar construction to indicate the unbalanced pressure exerted by the steam to impel the piston of the engine. The elastic force wherewith the steam acts above the piston (called the positive pressure or plenum) is shown by a common indicator, but the elastic force wherewith the uncondensed steam is at the same time reacting beneath the piston (called the negative pressure, or imperfect exhaustion or vacuum) is not shown; hence the observations are limited to two odd halves of the stroke made by the piston, those halves being commonly the plenum

during the descent, and the exhaustion during the ascent of the piston; it is taken for granted that the other two odd halves are the same as those which are observed, although such assumed parity is not always the true state of the case. In the new instrument the indication that it would make by drawing on a card, would be that of the difference subsisting between the plenum above, and the exhaustion beneath the piston of the engine, during its descent, and ascent, wherefore it would indicate on one card as much as two ordinary indicators can do on two cards, if they are applied one to the top and the other to the bottom of the cylinder of the steam-engine; in that case each indicator shows on its own card what the elastic force of the steam is during the plenum, and what it is during the exhaustion, but the required result (which is the difference between the two) must be obtained by combining together in the computation those distinct curved lines which are drawn on two separate cards. Professor Moseley's combined indicator pistons, acting on the same springs, would at once indicate such difference by the curve which it would trace on the one card.

In answer to a question from Mr. Parkes as to whether the new instrument had been put to any other test than its apparent agreement with Mr. Wicksteed's estimate of the resistance overcome; and whether the common indicator had been applied to the engine at the same time, Professor Moseley said that he had not compared the instrument with any other, but had subjected Mr. Wicksteed's calculations to a rigid investigation, and felt quite satisfied that they approximated closely to the truth. He relied upon them as corroborations of the accuracy of the instrument.

Mr. Parkes observed that it would have been more satisfactory to engineers to have been assured that every means had been taken to demonstrate the truth of the results recorded by an instrument which had such important functions in view. He wished to know in what manner the pressures denoted had been ascertained—whether by weights or by comparing them with a mercurial column. He had found the latter mode more exact than weights, in verifying the scale of the common indicator, as the instrument being heated was then in precisely the same state as when it was in use. He had found that a certain amount of correction was frequently necessary, as both the spring and the amount of piston friction were affected by heat.

Professor Moseley replied that the instrument had not been compared with the mercurial column, but that the resistance of the springs, and the friction of the piston and instrument generally, had been ascertained by very accurate experiments, so that he had full confidence in the results.

Mr. Parkes said that notwithstanding the respect and deference he felt for Professor Moseley's attainments and ingenuity, his past experience would not permit him to place entire confidence in the results afforded by the instrument; indeed he considered them to be altogether fallacious as representing the force acting on the piston of the Old Ford engine. He could not admit that the apparent near identity between Mr. Wicksteed's computations of resistance, and the constant indicator's registration of force, amounted to proof of the instrument's accuracy; for it seemed to him that Mr. Wicksteed had omitted to take into account one important item of force, without the exertion of which a piston could not be brought from a state of rest into a state of motion. He referred to the force required to give velocity to the piston. Mr. Wicksteed had weighed the greater part of that resistance which might be called ponderable, and had estimated the remainder, assigning about 12 lb. per square inch on the piston as the total amount, after deducting the resistance to the piston's descent arising from uncondensed steam. Thus, an elastic force of 12 lb. on the piston would counterpoise a resistance of 12 lb., but motion would not ensue until a superior force were applied. Considering the number of strokes made by this engine per minute, Mr. Parkes could not estimate the velocity of the piston at less than from 300 to 400 ft. per minute, which was very great for this enormous mass, and would require the exertion of proportionate power. He regarded the piston of the engine, loaded with 12 lb. per square inch, as he would a ball of 12 lb. weight in a gun balanced by a fluid of a corresponding elastic force; but such ball would remain motionless unless it were propelled by some additional force. This state of things had been denominated by Professor Barlow "the preparation for motion." Now as Mr. Wicksteed's estimate proceeded no further than the production of this state of things, and as Professor Moseley's constant Indicator recorded the mean pressure of the steam in the cylinder as barely equal to it, he could not assent to the accuracy of either method of determining the total resistance overcome by the steam.

Mr. Parkes would cite the experience of others as to the quantity of force actually expended in giving velocity in a Cornish engine, over and above that necessary to balance the weight at the opposite end of the beam, friction, &c. included. In the fifth part of Vol. III. Trans. Inst. C. E., Mr. Eys has reported some experiments made at Mr. Parkes' suggestion, on several engines. He would cite those of the Tresavean, as the cylinder was of the same diameter as the one at Old Ford, viz., 85 inches. The water load was equivalent to 12 lb. per square inch on the steam piston, and when about half the usual velocity was given to the piston in the in-door stroke, a pressure of about $17\frac{1}{2}$ lb. was denoted throughout the stroke, by a mercurial column connected with the cylinder. Mr. Loam had since transmitted to him the following abstract of experiments made on the same engine, January 28, 1842. "Two indicators were used at the same time, and an open mercurial gauge; the engine was held in-doors until the mercury became stationary, in order to ascertain the *minimum* quantity of steam power necessary to produce motion. The pressure was 15 lb. per square inch, when the water load was 12 lb." Here, then, a force of 3 lb. was found requisite to establish

an equilibrium between the power and resistance; and a further force of 2½ lb. per square inch was necessary in order to urge the mass at about the half of its ordinary velocity. Mr. Enys stated that less pressure was exhibited when the engine was brought in slower, and *vice versa*; and this was consistent with everyday experience. Now, though the Old Ford engine had not to overcome so much frictional resistance as a deep mine engine, yet, having a weight to raise, according to Mr. Wicksteed, alone equal to 11.8 lb. per square inch on the piston, Mr. Parkes was of opinion that this could not be effected at the usual working velocity, with less than 14 or 15 lb. pressure of steam per square inch. He would suggest to Mr. Wicksteed, to repeat Messrs. Enys and Loam's experiments, and also to work his engine with steam reduced nearly to such pressure in the boiler as would barely suffice to bring the piston down. Such experiments would confirm or invalidate the results given by Professor Moseley's instrument, and probably lead to the discovery of its imperfections, should any exist.

It appeared that Mr. Wicksteed conceived a greater amount of elastic force to be required to perform a stroke in proportion to the degree of expansion given to the steam in the cylinder. He would quote the pressures deduced by Mr. Wicksteed under five cases of expansion, as they exhibited some curious anomalies. They were taken from Table VI. of Mr. Wicksteed's Treatise. According to his table, when the steam was stopped at 6 ft. of the stroke, the mean force exerted during the stroke of 10 ft. was 13 lb. per square inch; at 4½ ft., 13½ lb.; at 4 ft., 14½ lb.; at 3½ ft., 15½ lb.; and at 3¼ ft., 15½ lb. It must be observed that in every one of these cases, the resistance, as appreciated by Mr. Wicksteed, amounting to 13 lb. per square inch, was a constant quantity; so that, for some unexplained reason, an invariable load appeared to require a variable force to overcome it; a sliding scale of power, given as the measure of a constant resistance. It was possible that some small difference might have existed in the velocity of the stroke, in these cases; it was also possible that some error existed in the method used for determining the pressures, or in the evaporative quantities. However this might be, it was clear there was an error somewhere, as it could not be granted that an effect deemed constant in all these cases could require a varying cause for its production.

As these appreciations differed widely from each other, and still more so from the indications of Professor Moseley's instrument, Mr. Parkes hoped that Mr. Wicksteed would re-consider and verify this part of the subject. In corroboration of his opinion that the acting force recorded by the instrument is too low, he would draw attention to the circumstance that, during the period of its application (28 days), the duty performed by the engine for each 94 lb. of coal amounted only to about 68½ millions, and it would not be unreasonable to expect that at least 150 millions should have been the result under the different circumstances of mine and water-works engines, as 100 millions had been performed for some months by mine engines under a water load equal to 12 lb., and a mean steam pressure of 18 lb. per square inch of the piston. Whereas, if the water-load of 11 lb. at Old Ford was overcome by an amount of force little exceeding 12 lb. per square inch, a proportionate increase of duty ought to have resulted, but such was not the case.

Mr. Parkes then proceeded to comment on the phrase "*effective power*," which he understood from Professor Moseley, as significant of the force of the steam, or piston pressure, measured by his instrument. He thought that phrase more strictly applicable to the amount of power given off by the engine, when ascertained, as it might be in the case of pumping engines, by the weight raised; or, as it could only be determined on rotative engines driving machinery, by a dynamometer applied at the extremity of the crank shaft. He would illustrate this by an example. There was at Birmingham a corn-mill belonging to Mr. Lucy, worked by an excellent engine of 40 H.P., made by Messrs. Boulton and Watt. This engine had a fly-wheel weighing 24 tons, and nine pairs of stones were driven, besides dressing-machines. Mr. Lucy had taken out a patent for an apparatus as a substitute for the fly-wheel, which had been removed. The engine so altered now drives ten pairs of stones, under the same pressure of steam, and with the same consumption of fuel as before. Thus, what he should denominate the "*effective power*" of the engine was increased, by this simple change, eleven per cent. Yet Professor Moseley's instrument, or any other indicator, would have exhibited, both before and after the alteration, the exertion of a precisely equal force on the piston. Neither did the Professor's instrument register the *absolute*, or what Professor Whewell had denominated the "*labouring*" force of the steam on the piston of an engine, as it made no deduction of the amount of force, whatever it might be, which was necessarily expended in overcoming the resistance opposed by the uncondensed steam. Its construction permitted it only to record the difference of these amounts. For these reasons he could not regard the instrument as likely, even when made trustworthy, to become of that utility to engineers which was the Professor's aim and hope. There was a greater need of an accurate dynamometer capable of showing the effective power of an engine whilst in regular work, and he was happy to say that this desideratum had been supplied by Mr. Davies of Birmingham, by whose permission he would take an early opportunity of describing to the Institution the construction and efficacy of this instrument. It was very important that a self-registering machine should be made, capable of recording the mean steam pressure operating throughout a stroke of the engine, but it was still more important that this registration should be accurate; and he hoped that the remarks which had been made would only urge Professor Moseley to farther investi-

gations, and induce him to enlarge as much as possible the useful powers of the instrument.

Professor Moseley observed that when a body passes from a state of rest, through a state of motion and into a state of rest again, or from a state of motion at a given velocity through a state of motion at a different velocity, and back to its first velocity again, then is the work which must be done upon it by the moving power the same in amount, whatever may have been the velocity thus intervening between the two states of rest or of equal motion of the body, provided that the resistance opposed to its motion and the space through which that resistance is overcome be in all cases the same.* In Mr. Wicksteed's engine the resistance thus opposed to the motion of the piston, and the space through which that resistance is overcome at every stroke, are thus constantly the same (or in other words, the work done upon the resistance is the same at every stroke of the engine), and the piston passes at every stroke from a state of rest, to a state of rest again; it follows therefore by the above well-known principle of "*vis viva*," that the work done by the steam, as the moving power upon the piston of the engine whilst it completes a stroke, is the same, whatever may be the velocity communicated to it, and to the mass which it carries with it, at any period of the stroke. It is true that to put the piston, and the mass carried along with it, at first in motion, a pressure greater than the resistance is required, and therefore greater than the mean pressure necessary to complete the stroke; a pressure equal to the resistance would only bring it into the state of rest bordering upon motion; to cause it to pass from this state of rest to a state of motion, more pressure is required, and the more as the velocity to be acquired, whilst it moves through a given space, is greater; or in other words, in order to communicate any given velocity to a body whilst it moves through any space, there must be an excess of the work done by the driving pressure through that space, over that expended upon the resistance through that space; but all this excess is accumulated, and unless the steam pressure be afterwards made less than the resistance, or unless the steam be afterwards expanded through a distance dependent on the amount of this accumulated work, so that it may expend itself in overcoming the surplus resistance through that space, then the piston will strike upon the cylinder bottom. This principle may be illustrated by an example; suppose that the load upon the piston of an engine is 10 lb. per square inch, and that the steam is admitted at a pressure of 15 lb., it is evident that by reason of the excess of 5 lb. pressure of the steam above the load, the velocity of the piston will be made continually to increase until the steam is cut off, and afterwards, so long as the steam pressure exceeds the load, or until by its expansion the steam pressure is reduced to 10 lb. per square inch. Up to this point the velocity of the piston and of the mass moving with it will continually have been increasing, a great momentum will therefore have been acquired by it, and this momentum will carry it on to the completion of the stroke; although after this position is passed, the steam pressure will be less than the load, and would by itself be insufficient to remove it. In other words, the work done by the steam upon the piston will have continually exceeded that expended on the load up to this period of the stroke, and the surplus will have been accumulated in the moving mass,† which surplus work will carry on the piston to the end of the stroke when a cylinder full of steam will be delivered of greatly less pressure than the load. If the steam had been worked at full pressure, it is evident that at every stroke a cylinder full of steam would have been discharged of the same pressure as the load. In this consists, therefore, the advantage of working expansively. It is evident that the piston acquires its maximum velocity at the point where the steam pressure becomes equal to the load, and that the engineer, by the manipulation of the steam valves, produces that adjustment by which the velocity acquired by the piston at this point (or the work then accumulated in it) is caused to be just sufficient to carry on the piston to the end of the stroke, but without striking the cylinder bottom; it is moreover evident that the greater this maximum velocity can be made, the farther the piston will be carried beyond the point where the steam pressure is equal to the load, and the less will be the pressure of the cylinder full of steam discharged at the completion of every stroke, or the greater the economy of the steam power.

A second illustration of the same principle may be drawn from the effect produced by a pressure suddenly thrown upon a spring. Suppose a spring which would rest deflected through an inch under a pressure of one pound. If when this spring is in an undeflected state this pressure of one pound be suddenly thrown upon it, it is certain that the spring will, at first, deflect considerably beyond that distance of one inch in which its deflection will eventually, after many oscillations, terminate. In fact, if it is thrown on with mathematical suddenness, the first deflection will be two inches. To

* This is a principle well known to mathematicians as resulting immediately from the principle of "*vis viva*," and is as old as the days of D'Alembert; it appears first to have been applied to questions of practical mechanics by MM. Coriolis and Poncelet.

† The number of units of work thus accumulated is represented in lb. one foot high by $\frac{1}{2} w v^2$; whence w represents the number of lb. in the weight of the moving mass, v its velocity in feet per second reduced to the piston $g = 32\frac{1}{2}$ lb. The expression $\frac{1}{2} w v^2$ is said to represent the "*vis viva*"; so that the accumulated work is equal to half the *vis viva*.

explain this, let the pound weight be supposed to be applied gradually to the spring by dropping grain after grain of sand slowly upon it. The spring will then evidently be brought to its deflection without ever passing it. Now let it be observed that on this supposition the first grain of sand only will have descended through one inch, the next descending through less than an inch, the next through yet less, and so on. Thus the work done upon the spring by each succeeding grain will be less than that done by the preceding. Yet the aggregate work done by these successive small pressures, each working through a different space, is sufficient to deflect the spring one inch. Now let all the grains be placed at once upon the spring. When it has deflected an inch, each grain will then have worked through an inch, and a great deal more work will, on the whole, have been done on the spring than before, indeed twice as much; but the work done before was enough to deflect the spring an inch; more than enough to deflect it has now therefore been done, that is, more has been done than has been expended. The remainder is accumulated in the moving mass of the sand and the spring, and carries on the deflection greatly beyond the position of equilibrium.

The Indicator was placed upon the engine of the East London Water-works, in the belief that by the experiments of Mr. Wicksteed, the work actually performed by that engine was better known than that of any other. All the calculations and inquiries which have since been made have fully confirmed that opinion. And he had full confidence in that verification of the registration of the Indicator which is supplied by its agreement with Mr. Wicksteed's estimate of the work of his engine.

In reference to the use of the term "work," Professor Moseley stated, that the various terms used by foreign engineers to convey the idea attached to that term, appeared at length to have resolved themselves into the single term "travail;" and that of the variety of corresponding terms used in England, the term "work" was probably the most obvious translation of "travail;" that it moreover appeared to him the simplest and the most intelligible; and that on these grounds he had adopted it.

In answer to the observation made by Mr. Parke suggesting the construction of an indicator which would register the work of the machine at the point where it is applied, instead of at the cylinder of the engine, Professor Moseley stated that such an instrument would undoubtedly be very valuable, especially if it could be made to register correctly the work transmitted by a rotating shaft; but that for the purpose contemplated by him it would be entirely useless—this object was to effect, in respect to ordinary engines working under constantly variable pressures, that constant registration of the duty, the introduction and publication of which had led to so remarkable an economy of steam power in the working of the Cornish engines. No registration of the work done at the working points of the machine driven by the engine, would supply a fair estimate of the duty done by the engine; a greater or less portion of the work done by the engine being lost by reason of friction in its transfer through the machine, from its driving to its working points, according as there was a greater or less complication of moving parts and rubbing surfaces intervening. He repeated that his object had been to determine the working qualities of the engine itself; and that he had for this reason specially sought to eliminate from his estimate those very influences of the friction of the machine driven by the engine which Mr. Parke thought it so important to include in it. It would have been a fault of his Indicator (for the purpose contemplated by it) if it had taken any notice of the effect of that change made in the machinery of Mr. Lucy's mill, which Mr. Parke had spoken of. He had used the term *effective work* (not *effective power*) of the engine, to signify that excess of the work of the steam on one side of the piston, over that opposed to it by the imperfectly condensed steam on the other, which it was necessary to know in order to estimate the real duty of the engine. It was solely for the determination of that duty that the Indicator had been constructed, and the alterations which Mr. Parke had suggested would have subjected its registration to influences which, in reference to that purpose, he had specially sought to eliminate.

Mr. Farey remarked, that it would lead to an incorrect appreciation of the merit of the new indicating instrument, if it were to be considered merely as a substitute for the ordinary indicator, when in fact they are two instruments, adapted to and equally useful for different purposes. The new instrument does not preserve any record of the minute details of any one stroke, like the ordinary indicator, but it records a true aggregate of all the details of any number of succeeding strokes; it gives the same results as would be obtained if it were possible to have two ordinary indicator cards correctly taken, at each succeeding stroke of the engine, during the whole time of observation, by means of two indicators, one of them applied to the upper, and the other to the lower end of the cylinder; and also provided, that an accurate admeasurement of every one of all those cards was afterwards made, at ten places in the length of the card, by the scale of pounds per square inch, in the usual manner, and the amount of the ten measurements added into one sum, and then (without averaging each card) that such sum of each card should be carried to a continuous account to obtain a grand sum total representing all the force that had been exerted, during both halves of each stroke made throughout the experiment, reckoned at ten stages or portions of the length of stroke. Such a grand total of all the cards would be a number representing the same fact, as is represented by the number shown by the new instrument; and would therefore be dealt with, in each case, in a similar manner, as one of the data (*viz.* that representing force) for calculating (by aid of other data representing motion or space) the whole power exerted during the time of observation.

In trying the performance of a steam vessel, alternately up and down a measured mile in the river Thames, it is usual to take an indicator card from each engine, at every such run; and by summing up each card, some difference will be found between them, wherefore an average of the results of several cards will give more authentic information respecting the force exerted by the engines during the whole trial, than could be obtained if one such card alone had been depended upon. The new instrument takes cognizance of every stroke that is made by the engine during the whole time of observation; and in cases (such as in the Great Western steamer) where a considerable variation of force in succeeding strokes occurs frequently during such time, it is a desideratum to obtain the results which this instrument is intended to give, and which, as far as it has been tried, it seems likely to give with fidelity.

The instrument when applied as it had been at Old Ford, becomes another mode of ascertaining performance, similar to what is reported monthly respecting the engines in Cornwall, but not exactly the same as is there called "duty," because the new instrument would show the aggregate of the unbalanced force, that had been exerted (during a given time) by the steam, to impel the piston; whilst the monthly reports show (by load in pounds, length of stroke in pumps, and number of strokes made) the aggregate of force exerted in the same time, in overcoming the resistance that the mere hydrostatic weight of the columns of water in the pumps, opposes to the motion of the engine.

The instrument ought always to show more force than the reports do, and the difference between the two, would be the aggregate of all the force that had been lost during the time, by friction of the moving parts of the engine, pumps, &c. Respecting that loss of force, there is no more of it than arises from such friction, from working the air-pumps, &c., and from resistance of the water, but it is wholly a mistake to suppose that any such loss is augmented by producing motion. Professor Moseley had just stated the true theory on that head, which theory was demonstrable mathematically, and admitted of no question. It would be needless to go further into what had been so well explained, except to observe that the theory applies without the least abatement, or modification by incidental causes, to the case of any machine which, like a steam engine, regains the same state, as to rest, (or as to motion) at the end of the time of observation upon it, as the state in which it was at the commencement of that time; and the theory shows that in such a machine, no part of the force exerted upon it (or exerted by it) can have been expended, or lost, in producing motion, whatever may be the number or the extent of changes or variations in velocity of motion, that the machine had undergone during the time of observation; for although force must be exerted to produce motion from a state of rest, yet all force that is so exerted will be rendered back again when the motion which was produced has ceased, and the state of rest regained; in the steam engine that is the case at the termination of every half-stroke. Respecting trials by means of the smallest force of steam, which will just press the piston of a pumping engine slowly down in the cylinder, or cause the engine to come creeping in-doors: they are not much to be depended upon as evidence of the force that is actually lost in overcoming friction; first because no steadiness of exhaustion can be kept up beneath the piston, nor steadiness of steam above the piston, whilst the engine is so treated, and also because the counterweight of engines in Cornwall is not apportioned with any great nicety. In general they are worked with more counterweight than is requisite, and but little loss is occasioned by so doing; for if the counterweight is unnecessarily great, so as to carry the engine quick out of doors (that is, to cause the pump-rod to descend briskly) then the equilibrium valve is closed sooner, and therefore retains more steam between the top of the piston and the cover of the cylinder, in what has been called the steam cushion, which stops the descending motion of the pump-rod; and in consequence of more steam being reserved in such cushion to go towards the supply for the succeeding stroke, that increase in the reserved steam compensates in part for the waste of force occasioned by the redundancy of counterweight, which caused the quick motion.

Mr. Farey had received from Mr. John Taylor indicator cards of Taylor's engine at the United Mines; one card was taken soon after it was first set to work, with an extravagant counterweight, and another card was taken immediately after several tons of balance had been added without alteration of the load of water in the pumps; balance in Cornwall is contrary to counterweight, so that adding balance effects a reduction of counterweight. Now if an attempt had been made to ascertain the friction of that engine by trying what strength of steam would cause the engine to creep in-doors, the day before the balance was added, the friction would have appeared (by that mode) to have been 3 lbs. or 4 lbs. per square inch greater than it would have appeared to be after the balance had been added; although that was an extreme case not likely to occur often, yet errors in the imputed amount of friction, to the extent of 1 lb. or 1½ lb. per square inch would be continually made, if dependence were to be placed on that mode of trial of engines working with so much counterweight as they may happen to have. The friction of modern engines in Cornwall, including that of their pit-work and pump, and the resistance of the water, he believed would not be found materially, if any, greater, than was the case in Mr. Watt's old engines, when the depth of the mines was not half as great, and the weight of moving parts not one-third as great; for the improvement in pit-work and pumps, and engine-work, had kept pace with that increase of depth and weight. The pump-rods are hung more truly perpendicular, and the lengths of timber for the rods are better jointed so as to cause them to hang straighter in the pit whilst working, and avoid lateral vibratory flexure, and therefore the rods rub less against their guides: the plungers are set truer, and being of large diameter, have less rubbing surface in proportion to their contents, the lifts being higher, and short lifts being avoided; these and many other improvements tend to reduce the friction in proportion to the force exerted.

The small quantity of steam expended, and consequently of water injected into the condensers, as well as better joints to prevent leakage of air into the

exhausted parts reduces the power required to work the air-pump to a smaller proportion of power exerted by the engine than formerly. And in particular the valves and water-ways through the pumps are made more open than formerly, so as to diminish the loss of force that is occasioned by resistance of the water; that loss of force by resistance increases as the square of the velocity of the motion, when loss of force by mere friction does not increase by increase of that velocity. He believed few large engines in Cornwall, which are making what is now thought tolerably good performance, lose more than at the rate of 3 lbs. per square inch of the piston, by friction of their moving parts, and by resistance of the water, and by working their air-pumps, and the best and newest engines probably still less. It would of course be understood that he meant by 3 lbs. what is commonly called $1\frac{1}{4}$ lb. for moving the engine each way, or through each half stroke; but that is not a correct way of stating it; $1\frac{1}{4}$ lb. friction in coming in-doors, and $1\frac{1}{4}$ lb. friction and resistance of water in going out-of-doors, would be more likely to be correct. With all that has been done in Cornwall, these matters still admit of further improvement.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

TWELFTH MEETING, 1842.

[We are indebted for the following report partly to our own correspondents, and partly to the *Athenæum* and the *Manchester Guardian*—the latter paper gave a very copious account of the whole of the proceedings, including the speeches delivered at the dinner.]

REPORT FROM THE COMMITTEE ON RAILWAY SECTIONS, presented by Professor Vignoles.

A grant of 200l. from this Association was made at the Glasgow meeting in 1840, on a joint application from the Geological and the Mechanical Sections, towards obtaining profiles of the various railways, chiefly with a view of putting on record (before the slopes of the excavations become soiled over and covered with vegetation) the geological appearances and strata developed in the many vast openings made through the country by the operations of modern engineering. At the Devonport meeting last year a renewal of the unappropriated balance of the first grant was made; the whole sum has since been expended, and the results are now laid before the Sections originating the subject, in the shape of the numerous working plans and sections of several of the railways, and of the enlarged parts of the profiles of the excavations.

In obtaining these the Committee appointed by the Association have great pleasure in reporting, that they have been aided in the most effective and satisfactory manner by all the railway companies to whom they have applied, and also by their several officers, the engineers in particular having taken extreme pains and great interest in forwarding the views of the Association. When so many parties have thus zealously co-operated, it might be almost invidious to name one without specifying all; but in particularly mentioning Mr. Swanwick, the engineer of the North Midland Railway, the Committee wish to do so for the purpose of remarking on the great pains taken by that gentleman in marking, as his works went on, all the geological details of the cuttings, which pass through so interesting a region, and which has put into the possession of the Committee a vast extent of most valuable records of the kind sought for, and which at the same time forms a most striking example, well worthy of imitation, of the combination of engineering and geological information, applicable for economic purposes.

The Committee were not at first able to organise a system of working the grant to their entire satisfaction; but they found after some experience that, with the favourable disposition shown by all the railway companies, they might (without increasing the expense,) by degrees and in no great time, be able to form an interesting and valuable collection, not only of the sections of the excavations of the railways, but of the whole of the plans and profiles of all the lines, which, concentrated in one public depository, and open to the inspection of all scientific and literary bodies and individuals, and to the public in general, under proper regulations, would be of high interest. In fact such documents were almost necessarily required, as the mere indices whereby to identify the particular geological profiles; and so useful and important is such a collection likely to become, that it is not unreasonable for the Committee to hope and believe, that after another year's experience shall have matured their arrangements and perfected their proposed system of records, and brought down the expense to a certain and moderate rate per mile, the subject may be taken up by Her Majesty's Government, and made to form part of the great geological survey of the United Kingdom, conducted by Sir Henry De la Beche, in connection with the trigonometrical survey now carrying on by Colonel Colley and the officers of the corps of Royal Engineers. The Committee, therefore, are not without hopes that the geological and mechanical Sections will again unite in applying to the General Committee for a further grant of 200l. at the

present meeting, to enable them to complete the organization they have begun.

The documents which the Committee have to submit are the following:—

1st. Plans and sections of the whole of the Midland Counties Railway from Rugby to Derby and Nottingham, about 58 miles. Enlarged sections of the cuttings on that railway, prepared to be filled in geologically. The chief characteristics of this district are the gypsum beds, commonly called plaster of Paris, and the hydraulic lime, well known to engineers as the Barrow lime.

2nd. Plans and sections of the whole of the North Midland Railway, from Derby to Leeds, about 72 miles. The entire of the geological details have been laid down on the working sections of the cuttings; but as it has been considered by the Committee that a uniform system should be observed enlarged sections have been prepared, on which, as on the similar sections of the other lines, the strata should be delineated. It may be observed here, that these enlarged sections are on the natural scale of 40 ft. to an inch, that is, the vertical and horizontal scale are alike, which is not always the case in ordinary geological sections, and very seldom so with the working sections, for earth work and similar engineering purposes. This railway intersects the coal districts for many miles, and is replete with interesting objects.

3rd. Plans and sections of the Manchester and Leeds Railway, from Manchester to Normanton, about 50 miles. These latter are not quite finished, but will be so before the close of this meeting. Enlarged sections of a considerable portion of the excavations on this railway, are filled up with the geological details.

4th. Enlarged sections of the excavations on the Glasgow, Paisley, and Greenock Railway, about 22½ miles, with the geological details.

5th. The same for the Manchester and Bolton Railway, about 10 miles, containing full details of the strata where the remarkable fossil trees were found, and of the trees also, models of which are in the exhibition room at the Royal Institution in Manchester. The liberality of this company will afford several opportunities for the members of the Association to visit these trees, and the particular profile of the excavation where they are will remain in the Geological Section, or in the Royal Institution, where the models are.

6th. Enlarged sections of the Hull and Selby Railway, about 30½ miles, with the geological details.

Some other enlarged sections are stated to be preparing for the Committee, but they have not come to hand in time for the present report.

These records, according to the directions of the Association, will be deposited in the Museum of Economic Geology, in London, where they may at all times hereafter be usefully referred to.

In conclusion the Committee cannot refrain from observing that the documents thus collected are equally important and interesting to the philosopher, the geologist, and the engineer. To the philosophical or theoretical investigator they present the curious and varying features of the crust of this portion of the globe; to the practical engineer they offer a memorial of the experience of the profession, whence many a serviceable lesson for future operations may be learned; whereby difficulties and expense may be hereafter avoided and diminished, and from which valuable information may be derived for the appliance of materials in constructions, it being one of the great arts of the engineer to avail himself of the most immediate natural resources which he has to displace in one instance, and to apply them usefully in another, when in juxta-position. And, on the other hand, the minute variations of strata and soil thus accurately delineated, and referred to well-defined altitudes, with respect to the general surface of the ocean, become of the very highest interest to the geologist, and no less so to the mining engineer, more especially on the lines of railway intersecting the coal and mineral districts, where, in numerous instances, labour, directed by science and sustained by commercial enterprise, has laid bare in deep chasms the secrets of Nature, and the stores whence this country has derived so many advantages, and whose well-directed energies have drawn from our mines of coal and rude metals that abundant wealth and prosperity which the more splendid productions of Potosi and Mexico have failed to bestow on their possessors.

ON STRAIGHT AXLES FOR LOCOMOTIVES, by Prof. Vignoles.

The fatal results of the late terrible catastrophe on the Paris and Versailles Railway (rive gauche) has drawn the attention of the public in general and engineers in particular, to the causes which produce such fearful effects; and the breaking of the axle having been prominently put forward as the original occasion of this and many other railway accidents, it seems desirable that a dispassionate inquiry should be instituted, and an endeavour made by calm discussion to elucidate truth.

It is not intended, in the present note, to allude, except in general terms to the above accident. It is clear that the breaking of the axles in this case was not of itself sufficient to produce such a disaster. It was not the driving axle that broke, but the fore axle of the small four-wheeled engine; and it

was with great regret that I perceived the cause of the accident attributed to the principle of construction of the machine. It must be quite evident to all engineers who have attentively read the details of the accident on the Versailles Railway, and of the one that occurred on the London and Brighton Railway soon after the first opening, that the same causes were in operation, and greatly aggravated the sad results in both instances, viz. the coupling together of two locomotive engines of unequal power and of different constructions, the smaller in advance:—On both occasions a long train of heavily laden carriages were moving at very high velocities on a falling gradient; on the occurrence of the accident to the smaller engine in front, the driver suddenly turns off the steam; the man on the larger engine behind, from whatever cause, does not act simultaneously, and a few seconds continuance of the vast unchecked momentum of the heavy engine with the steam on, overwhelms the smaller machine, and the whole train is overthrown. It is scarcely possible to regulate this unity of action, more especially in the locomotives of unequal size and construction. Why are engines propelling from behind objected to? Evidently because, in the event of any obstacle occurring in front, a simultaneous check cannot be given to the rear engine, and it drives the carriages forward upon each other, at the very moment when the opposite effect is required.

There is, therefore, quite sufficient to account for the accidents in both cases, without raising the ridiculous and exaggerated cry against the four-wheeled engine *per se*. As respects safety to the travelling public, I believe, and I venture to say, in common with a great many engineers who are not manufacturers, that there is no material difference between the four-wheeled and the six-wheeled locomotives; but that the consideration most generally influencing the selection is that of the distribution of the weight of the machine, so as to impinge less injuriously on the rails; and it is well understood that the system of the double trucks, or eight-wheeled supports for locomotives, tenders, &c., as adopted on the American Railways, has been introduced on this principle, the rails and upper works in that country being in general much lighter than with us.

The real and important point, and which seems to have been quite lost sight of in the vivacious discussions on what I would call the minor question of the number of wheels, is, whether the *cranked axles* for the driving wheels of locomotive engines ought not to be abandoned, and whether driving axles should not be always made straight. The extent of prejudice in favour of cranked axles is most extraordinary. The very great increased expense incurred in making and strengthening them, the additional complexity and cramping into narrower space of all the moving parts of the machinery, and the consequent wear and tear and inconvenience involved by their use, to say nothing of the augmented risk, far overbalance, in my opinion, any theoretical advantages alleged in their favour, but which advantages and superiority, in practice, over the straight axle engine, I could never discover and wholly deny. Eight years since, after a hard struggle with the manufacturers, straight driving axles were adopted for the locomotives on the Dublin and Kingstown Railway. On that line, especially on Sundays and on holidays, the traffic is quite equal to that on any railway yet open. Trains of from 12 to 15 carriages (but with one engine only) are at such times sent every quarter of an hour from each end of the line; and there has been no instance of accident from any cause connected with the form of engine or axle, or with such frequent departure of heavily laden passenger trains; and the finance accounts of the Company show that the cost of locomotive power, repairs, &c. is below that of other lines using cranked axles; nor do I know of any cause of objection to the straight driving axle, after seven or eight years experience of their use, without, I believe, a single instance of failure which fully justifies my opinion of their superiority.

On other railways I have been connected with I have not always been so fortunate as to have succeeded in banishing the cranked axle. As sometimes happens in Governmental and political struggles, the votes of the controlling body have overpowered the opinion of the executive, where a difference among members of our profession have given opportunities for Directors to exercise their own discretion; and cranked or straight axles, four-wheeled or six-wheeled engines, have been alternately adopted according to the prevailing ideas of the majority of the several railway boards.

I have, however, reason to believe that several engineers of high standing are becoming converts to the straight axle, and I congratulate the public on it, as a very important step in the right direction.

In respect to the attention to be given to the manufacture of axles, it is impossible to pay sufficient regard to the importance that the scrap iron should not only be of very good, but also of exactly similar quality, and that each scrap should have gone through the same processes in its previous different stages. On this subject I hope some of the experienced manufacturers who are present will throw some light, especially on the details, for on the abstract principle there can be no dispute, although I suspect it is greatly neglected, in particular for ordinary carriage axles, and probably only scrupulously attended to in forming the driving axles of locomotives.

Some of the French engineers, however, have, within a very recent period, suggested that we must seek for the causes of the often unexplained rupture

of axles in another way. M. François and Colonel Aubert have both lately read, at the Royal Academy of Paris, papers on the subject, and attribute the cause of the fracture of the axle of the engine on the Versailles Railway to the iron having been crystallized from the action of heat or magnetism. In support of this opinion it is stated that the axle broken was formed of the best iron, and was of sufficient dimensions; and that the fracture had a decided crystallized appearance: and I have indeed myself often observed the same character in broken axles, so much so as to induce me to fancy sometimes that they had been formed of cast iron.

M. François stated in his paper that he had made a long continued series of experiments, and had observed that a magnetic action on iron in a state of fusion will produce similar effects, and change the small and closely adhering particles into coarse and large crystallized grains, depriving the iron of its compact character. This talented mineral engineer inferred that the action of heat upon axles moving at high velocities might produce the same effect. Both M. François and Colonel Aubert seemed to be of opinion that the only real precaution was to change the axles of locomotive engines so frequently as not to give them time to undergo the crystalline change; suggesting, however, that iron that had been previously worked up should alone be employed for axles, and not new iron, which had more of a vitreous character, and was more susceptible of crystallization.

Since this paper was prepared, I have reason to believe that this crystallization of wrought iron has been noticed by some of our eminent manufacturers, whose opinions there may be an opportunity of obtaining; and if it be, as Mr. Fairbairn informs me, that cold swaging will crystallize hammered iron, the shocks that locomotive engines sustain in their rapid transits may well be put as a great cause of this remarkable change.

It is, however, clear, that to remedy and replace straight axles is much easier and cheaper than to deal with cranked axles, and I venture to state it as my humble opinion, that as much ingenuity and talent is thrown away in arranging locomotive engines with cranked axles, and in perfecting the manufacture of those "crooked billets," as there was in rolling iron into undulations for fish-bellied rails; which are now almost as much forgotten as, I doubt not, the cranked axles for locomotive engines will one day be.

Remarks.—Mr. Hodgkinson was certain, from the results of his experiments, that a succession of strains, however slight, would produce a permanent deterioration of the elasticity of the iron.—Mr. Fairbairn had been told by the engineer on the Leeds line, that he considered all crank axles to be constantly deteriorating from percussions, strains, &c., and that they should be removed and replaced by new ones periodically, to avoid danger of fracture.—A discussion arose as to whether the crystallized appearance observed in fractured axles arose from defects in the manufacture, in the quality of the iron, or from the effects of working, either by percussions, strains, or magnetic action.—Mr. Grantham, although a manufacturer of cranked axles, admitted that straight axles were less liable to break. Cranked axles, from the way in which they were welded together and shaped, were rendered weak and liable to fracture. On other grounds, however, he believed that the cranked axles were preferable, as they produced a steadier motion, and much heat was saved.—Mr. Garnett believed that more straight axles had broken than cranked ones.—Prof. Willis showed the effect of vibration in destroying molecular arrangement, by reference to the tongues in musical boxes, &c.—Mr. Nasmyth believed that the defects in axles, &c., arose in the manufacture, especially from cold swaging and hammering, and also from over-heating in welding, all of which causes injured the toughness of the iron. In small articles he found great advantage from annealing; and he believed that axles might be annealed very cheaply, and would be more serviceable. He disliked the fashion of referring all unaccounted phenomena to magnetism and electricity, although he was convinced that very singular electric phenomena accompanied the transit of locomotives and the rapid generation of steam. With this was connected the non-oxidation of rails, where the traffic was in one direction, and the rapid oxidation when the same rails were travelled over in both directions, as in the Blackwall railway. He had also observed that brasses, in some cases, had from friction entered into *cold fusion*—that is, at a heat not perceptible to the eye, a complete disintegration of the molecular structure had taken place, and he had seen the brass spread as if it had been butter or pitch. He had no doubt that this arose from electricity, but had not ascertained the fact from experiment.—Mr. Fairbairn stated, that in hand-hammered rivets the heads frequently dropped off, and presented a crystallized appearance, while those compressed by machine were sound. He found that repeated percussions, from the rivetting, hammering plates, &c., induced magnetism in iron boats.—Mr. Vignoles could not, from his experience, agree to Mr. Nasmyth's theory of the oxidation of rails by single traffic, as the railway from Newton to Wigan had been single for a long time, and was as bright as the Manchester and Liverpool. The Blackwall railway was not an analogous case, as no locomotives were employed.—Mr. Roberts disbelieved the deterioration of axles by work; he would rather trust an old axle than a new one. He believed cold swaging and hammering to be the chief causes of mischief. In fact, if axles were sent out sound and well manufactured, they would rather improve by working.

Mr. Nasmyth at a subsequent meeting gave some valuable practical suggestions on the cause of breaking of axles, which we purpose noticing next month.

ON THE ACTION OF AIR AND WATER ON IRON. By Mr. Mallet.

This is the third report for which the association is indebted to Mr. Mallet. The object of former tabulated results was to determine the actual loss by corrosion in a given time, and the comparative durabilities of rust of the principal kinds of cast iron of Great Britain, and to discover on what durability depended. The tables of experiments now presented show that the rate of corrosion is a decreasing one in most cases, and that the rapidity of the corrosion in cast iron is not so much dependent upon the chemical constitution of the metal as upon its state of crystalline arrangement, and the condition of its constituent carbon. The present report, too, extends the inquiry to wrought iron and steel, of which between thirty and forty varieties have been submitted to experiment. The results show that the rate of corrosion of wrought iron is in general much more rapid than that of cast iron or of steel. The finer the wrought iron is, and the more perfectly uniform in texture, the slower and the more uniform is its corrosion. Steel corrodes in general more slowly, and much more uniformly, than wrought or cast iron. The results of the action of air and water in the several classes of iron have been examined and chemically determined. The substance spoken of as plumbago was next described. It is produced by the action of air and water on cast steel, especially that in the raw ingot, in the same way as it is in the case of cast iron.

A quantity of plumbago, found in the wreck of the *Royal George*, absorbed oxygen on exposure to the air with such rapidity, that it became nearly red-hot. Mr. Mallet next described a method of protecting iron by a modification of the zinc process. It was found impossible to cover the surface of iron with zinc, to which it had no affinity. The first process was to clean the surface of the iron, taking off the coat of oxide, and then immersing it in double chloride of zinc and ammonium, which covered it with a thin film of hydrogen, by which its affinity for the zinc is much increased. The iron was then covered with a triple alloy of zinc, sodium and mercury. Mr. Mallet produced several specimens of his alloy, one of a bolt to be driven into a ship's side, and another a cannon shot covered with his preparation, and exposed to the weather on the roof of a building, and which was perfectly preserved. Cannon balls were so much oxidised by exposure to atmospheric influences, that in five or six years they became useless. The French Institute had been engaged in experiments to protect these, and had been compelled to abandon it. Mr. Mallet also brought under the notice of the section a method of preventing the fouling which takes place on the bottoms of iron ships, especially in tropical climates, by means of which new invention he had ascertained plants and animals were prevented from adhering to the ship's bottom.

Another series of experiments related to the rate of corrosion of cast iron, wrought iron, and steel, exposed to atmospheric influences—a matter of great importance to the engineer. The characteristic form of corrosion in air, as contradistinguished from that of water, was also pointed out. This series of inquiries was now complete. The next matter which had engaged his attention was the rate of corrosion of rails on railways. The general opinion was, that the rails travelled over were not corroded at all. He had been enabled to lay down three sets of rails on the Dublin and Kingstown Railway: one not travelled over, the second in use and not exposed to corrosion, and the third also in use, but made impervious to moisture. The loss of the first was 2'555, of the second 2'344, and of the third 2'650,—results which seemed to indicate that the rail travelled over does corrode more slowly than that out of use. Mr. Mallet concluded by referring to Mr. Nasmyth's theory, that corrosion is checked by the trains passing over the rails always in one direction, and takes place when, as in the case of the London and Blackwall, trains pass both ways.

The Vice-President paid a high compliment to Mr. Mallet on the value of his investigations, and the success which had attended them. The cost to the association of these inquiries was far less perhaps than that incurred by Mr. Mallet in addition to the sum voted him; while the results might have been made more conducive to his private purposes, had Mr. Mallet chosen to conduct them for his private advantage. In reply to a member, Mr. Mallet said his preparation for the bottoms of iron vessels lasted for about two years and a half in Kingston harbour, in a vessel exposed to a rapid tide-way. He did not think his preparations would answer for copper sheathing. Nothing but copper would protect wood; but he looked forward to the time when the greater proportion of our vessels would be constructed of iron.

"On the mode of conducting experiments on the resistance of air." By Mr. Eaton Hodgkinson, F.R.S.

Mr. Hodgkinson said, that, having been honoured by the Association with a request to pursue some experiments on the resistance of the air, he was desirous of exhibiting an instrument prepared for making the first series of these experiments. He proposed, in the first instance, to seek for the force of the wind moving at different velocities, upon plane surfaces of given dimensions, these surfaces being either perpendicular, or inclined at any angle, to its current; to determine this, he intended to place the apparatus upon the front of the first carriage of a railway train; the road along which the train passed having for a short distance poles stuck up, one hundred or two hundred yards asunder. He would try the experiment only on days when there was no perceptible wind; and then, if the time in seconds, taken in passing between two poles, be carefully observed, and the pressure indicated upon the discs (which were of two feet and four feet area, both round and square), the resistance per square foot, with a given velocity, would be ob-

tained. He hoped to determine these facts, with various velocities and at different angles of inclination in the discs, trying the same experiments with both discs at the same time, to ascertain whether the resistance to a square surface and a round one, of equal area, was the same, and that the results might correct each other. It would then be determined how far the law of resistance of air to planes moving obliquely through it agreed with the theoretical suppositions hitherto in use. To apply the result of the proposed experiments to the case of bodies at rest, acted upon by the wind, he assumed that the resistance of a body moving with a given velocity through the air at rest, was the same as that of the wind moving with the same velocity, and acting upon the body at rest. The directors of the Manchester and Birmingham Railway had kindly consented, at Mr. Buck's request, to allow him to make these experiments; and he was indebted to Mr. Fairbairn for the apparatus.—This was placed on the table. It consists of two discs of wood (which may be round, square, or of any other form), made inclinable to any angle, by means of screws that fix them to their position, and having two straight rods moving in slots, and an attached quadrant to measure the angle. To ascertain the force of the wind, one of Salter's balance springs is placed behind each disc, attached to the cross piece which connects the two rods of the discs; and this indicated the force of the wind at any moment. Several suggestions were made as to the instrument, and the mode of trying the experiments; to which Mr. Hodgkinson said he would give every consideration.

EXPERIMENTAL INQUIRIES ON THE STRENGTH OF STONES AND OTHER MATERIALS. By Mr. Hodgkinson.

After noticing the present state of knowledge on this subject, and the experiments of Barlow, Rennie, and of other experimentalists on the continent, Mr. Hodgkinson said he had long felt anxious to ascertain how the three forces—the crushing, the tensile, and the transverse strength—and the position of the neutral line—(that separating the extended and compressed fibres in a bent body)—were connected in bodies generally; and his experiments had for several years been directed to discovering facts upon each of these matters, in order to determine the question. His experiments some years ago, made for the British Association, with respect to the values of hot and cold blast iron, had shown that the ratio of the forces of ultimate tension and compression was nearly constant in all the species of cast iron; and a few experiments made at that time on sandstone and marble, had led him to suspect that nearly the same would be the case in these and other hard bodies. Through the liberty of his friend Mr. Fairbairn (who had, as usual, given him every assistance his establishment afforded), he (Mr. Hodgkinson) had made a great many experiments upon wood, sandstones, marbles, glass, slate, ivory, bone, &c., to ascertain the tensile, crushing the transverse strength of each; also, as far as possible, the situation of the neutral line in thirteen different kinds of timber (including oaks, pines, teak, &c.) All the three sorts of experiments were made as far as possible out of the same specimen in each case, to render the results as unexceptionable as they could be made. The wood was of good quality and perfectly dry, having been chosen for this purpose, and laid in a warm dry place for four years or more. Previous to experiment, the bars of wood were all reduced with care to the same dimensions, and afterwards weighed, to ascertain the specific gravity. They were then laid upon supports to obtain the deflections with given weights, and the breaking weight with its deflection. The two portions into which a specimen was broken were afterwards reduced in the middle by the lathe to the form used in Mr. Barlow's experiments, in order that the experiments might be torn asunder in the middle, by a force acting directly through the axis, and thus to obtain the tensile strength of the wood. Afterwards, the thick ends of the specimens were turned by the lathe into cylinders, all of the same diameter and length, as nearly as practicable, and their exact dimensions afterwards taken, in order to ascertain by experiment the resistance of the woods to a crushing force. After describing the character and results of his experiments on the various substances named above (specimens of which he produced), Mr. Hodgkinson gave the following summary of results of very numerous experiments on marbles and stones of various degrees of hardness:—

Description of stone.	Crushing force per square inch called 1000.	
	Tensile force per sq. inch.	Transverse strength of bar 1 inch square, and 1 foot spaces.
Black marble	143	10.1
Italian marble	84	10.6
Rochdale flagstone	104	9.9
High Moor stone	100	
Stone called Yorkshire flag		9.5
Stone from Little Hulton, near Bolton	70	8.8
Mean rates	100	9.8

Mr. Hodgkinson gave the following recapitulation of results:—Calling the mean crushing strength per square inch, in the different articles experimented upon, 1000, we have—

	Tensile strength.	Transverse strength.	Ratio of mean transverse to one strong force.
In timber	1900	85.1	1.55
Cast iron	158	10.8	1.66
Glass (plate and crown) . .	123	10	1.78
Stone and marble	100	9.8	1.105 or 1.89, taking the hardest only.

The ratio of the crushing force to the transverse force is nearly the same in glass, stone and marble, including the hardest and the softest kinds. Hence if we know the transverse strength or the crushing strength in any of these bodies, we may predict the other; and, as glass and the hardest stones resist crushing with from seven to nine times the energy that they do being torn asunder, we may get an approximate value of the tensile force from the crushing force, or *vice versa*. These results render it probable that the hardest bodies, whether cast iron, glass, stone, or marble, admit of certain atomic displacements, either in tearing asunder or crushing, these displacements being in a given ratio to each other, or nearly so. In future calculations as to the strength of bodies, the crushing strength ought to be made the fundamental datum, which I have recently done, for the reasons shown in this notice. The ratio of the transverse strength to the crushing strength is greater in cast iron than in glass, marble, and sandstones, arising from the ductility of that metal. The necessity of enlarged inquiries in these matters will be seen, when it is reflected that calculations of the transverse strength of cast iron, or marble, or stones in general, made from the transverse strength by the modes used by Tredgold, Navier, and others, give the transverse strength twice or three times as great as it ought to be.

The Chairman said the section was greatly indebted to Mr. Hodgkinson for his very interesting communications. Those experiments had attracted much attention from scientific men, and the Royal Society had presented him their medal for a former paper on this subject. [We may here mention, that this communication was only some portion of a more full and perfect paper, to be read before the Royal Society; such communication being now made only as would not preclude Mr. Hodgkinson from laying the more complete results before that society.] He might also express the opinion of practical men, that no experiments, either as to extent, care, or accuracy of observation, gave results at all comparable in point of value with those of Mr. Hodgkinson, who, he hoped, would have the time and inclination to pursue his experiments to a greater extent. There were no results in practical science of greater importance than those which showed us the strength and stability of materials. In the structure of buildings, upon which the comfort and wealth of so many individuals depended, and in other structures in engineering operations—an ignorance of the important facts arrived at by Mr. Hodgkinson had, in many cases, led engineers to make structures disproportionately strong or weak; in the one case causing unnecessary waste of materials and unnecessary expense, in the other periling the stability of the structure, and the safety and lives of those within it.

The Rev. Dr. Peacock (Dean of Ely) then made an oral communication "Upon the report of the commissioners for the restoration of lost standards of weights and measures, and upon their proposal for the introduction of a decimal system" (during which communication Sir William Hamilton took the chair). After stating that the imperial standards of weights and measures (the yard, the lb., the gallon, and several of their multiples) had been lost in the fire which destroyed the two Houses of Parliament, he said that a commission (of which he was a member) had been appointed, to report on the best means of restoring these standards. He noticed the proceedings of a former commission, on whose recommendation the act of the 5th Geo. IV. had been passed, declaring the imperial standards of weights and measures, and prohibiting all others to be used, and pointed out the erroneous data on which that former commission had fixed the standard yard; by which data, therefore, the present commission did not recommend its restoration, but rather to take the extant copies of it, especially the one in the care of Mr. Francis Bailey, as the authority upon which the new standard yard should be formed. The commission also recommended to the government that the standards of length and weight should be independent of each other, which was not the case before. The standard pound weight was Troy weight (5780 grains), though the pound avoirdupois (7000 grains) was used throughout the country, in the proportion perhaps of 10,000 to one of Troy. The commission recommended the standard pound to be the representative of the avoirdupois, and not (as before) of the Troy pound; that, hereafter, the use of the Troy pound should be abolished, except for a very limited number of transactions, and that the avoirdupois pound should be considered as the standard pound of Great Britain. They recommended that measures of capacity should be determined by measures of weight—by far the most convenient method, inasmuch as weighing was a much more accurate operation than, for instance, the formation of a perfect cube. The commission also ventured to recommend strongly some alterations in the coinage, and the systems of weights and measures, arising out of a more extensive introduction of the decimal scale. The nearly unanimous determination of the commission was, that any attempt to interfere materially with the primary units of the coinage, weights, and measures, in ordinary use, would produce such confusion and bad consequences in the ordinary transactions of life, that they would adhere strictly to all those primary units, viz., the pound sterling of our coinage, the yard, in the measure of length (and also the foot, for there

were two primary units in this measure), the acre, in the measure of areas; the gallon, in the measure of capacity, and the imperial pound in the measure of weight. As the coinage must necessarily be the basis of any changes leading to the more extended adoption of a decimal scale—taking the pound sterling as the primary unit, they proposed to introduce a coin of the value of 2s. (one-tenth of the pound); another, either silver or copper, of one-tenth of 2s. (or 2d. and a fraction) which might be called a *cent* (the hundredth of a pound); and the thousandth part of the pound sterling, or nearly the value of our farthing (of which there are 960 in the pound), which new coin it was proposed to call a *millet* (from thousandth). The difference in the value of the copper coinage was less important, as it was merely a representative coinage, and had not an approximating intrinsic value, like the gold and silver coinage. For the proposed coin of 2s. various names had been suggested, as *Victorine*, rupee, or forin; it being not much different from the value of some of the rupees of the East Indies, or the florin of the Continent. Under this new decimal scale the shilling would be retained, and also the sixpence (but the latter under another name, more representative of its value). For the half-crown would be substituted the 2s. or *Victorine*. The very rev. gentleman dwelt at some length on the advantages of this change, in the extensive money transactions and accounts of bankers and merchants; in the Bank of England, for instance, where a thousand clerks were employed, where it would greatly facilitate the operations of calculation and book-keeping. Thus, discarding *millets* (for bankers now excluded the subdivisions of a penny in their accounts), the sum of £17 3 *Victorines*, 7 *cents*, would be represented at once by 17.37; only two places of decimals, instead of as now in pounds, shillings, and pence. He showed how the principle was applicable, with still greater advantage, in cases of weights and measures (where the scale was now most anomalous and absurd). Suppose the rental or value of 30.64 acres of land to be required, and that the land cost £69 3 *Victorines*, 4 *cents*, an acre. The reduction in common arithmetic was one of very considerable labour, difficulty, and time. Indeed, if this decimal system were adopted, the labour of teaching arithmetic to school boys would be reduced nearly one half. But by this plan (as the rev. doctor showed), the result might be obtained in five lines of decimals, containing only 21 figures. As to weights, the most extensive change recommended by the committee would be to introduce the uniform weight of 10 lb. to the stone, instead of the varieties of 8 lb. in some, and 14 lb. or 16 lb. in other parts of the kingdom; the hundred weight to be called *centna* (a German term). There were all the changes proposed in weights, the commission not wishing to interfere with the subdivision of the pound, which admitted of four subdivisions into 8 oz., 4 oz., 2 oz., and 1 oz. The pound and ounce would remain, therefore, exactly the same as at present. As to the measure of length, the commission thought it too violent a change to alter all the milestones; but there would be no difficulty (with reference to the standing orders of parliament, in railway matters, &c.) to introduce the measure of 1000 yards, which might be called a *milyard*. However, the commission made no recommendations as to nomenclature, leaving that to the legislature. Thus the changes proposed to be introduced, not only to ensure a decimal coinage, but a decimal subdivision of weights and measures, were by no means of that formidable and appalling character which many persons supposed they must of necessity possess.

On the use of Beton and Concrete in the construction of Breakwaters.

Mr. Vignoles called the attention of the section to the works now going on at Algiers, in the formation of breakwaters by the use of concrete, under the direction of M. Poirel, where he said a shelter had already been made for 15 sail of the line, at an expense, even under all the difficulties presented by the circumstances of that country, of about 20s. per cubic yard; and he had no doubt that in this country, in any situation where a good hydraulic lime could readily be procured, the expense would not exceed 10s. per cubic yard. Some very extensive works of the same kind had also been executed at Marseilles. Mr. Philip Taylor, of Marseilles, in confirmation of Mr. Vignoles, mentioned several instances in which concrete was used in that neighbourhood, with the greatest success. He stated that *béton* was a material much used in that vicinity, though scarcely known in England. It was composed of one part of ground brick, and two parts of lime. Mr. Smith, Mr. Fairbairn, and several other gentlemen, expressed their opinions as to the value of concrete, and its applicability to a variety of purposes to which it was not commonly applied.

Mr. Scott Russell's Index for the speed of Steam Vessels.

Mr. Russell stated, that his index of speed was founded on the well-known dynamical fact, that if an aperture were made in the lower part of a vessel containing water, and a stream were allowed to issue from it against an aperture in another vessel containing water, the force of the current would keep the water in the second vessel at the same height as in the vessel from which the current issued. It would follow, from this principle, that if a vessel were passing through the water at a speed equivalent to that of the current produced by a given head of water, the resistance would raise water in a tube inside the vessel, but subjected to the action of the external fluid. Mr. Russell then proceeded to detail the particulars of the invention to which he had applied this principle, by passing a tube through the bow of the vessel, and carrying it along the flooring to the centre of gravity of the vessel, where it terminated in a

vertical glass tube, exhibiting the weight of water within. To this tube there was attached a moveable scale, the zero of which being placed on a level with the point at which the water stood when the vessel was at rest, the rise of the water in the tube when the vessel was set in motion exhibited the velocity at which the vessel was passing through the water. With the view of testing the accuracy of this invention, he had tried it repeatedly over a distance of 15 miles, measured trigonometrically. He had also compared it with the best logs, and was perfectly satisfied of its accuracy. From these experiments he had constructed a scale, which he exhibited, and of which the following is a copy; the first column exhibiting the speed in miles per hour, and the second the height of the water in the tube above the zero line expressed in feet and decimal parts:—

Miles per hour.	Feet on the scale.

A NEW SELF-ACTING WEIR AND SCOURING SLUICE, by Mr. Bateman.

Mr. Bateman observed that the great objections to fixed weirs and dams were, that by causing a partial stagnation in the water above them, they allowed the bed of the stream to be silted up by the deposition of mud, gravel, &c., whereas the proposed weir would adjust itself to the various changes in the condition of the stream, and prevent any filling up of the channel by making the stream clear itself. Mr. Bateman's weir is composed of two leaves turning horizontally on pivots, which are placed below the centres of the leaves, so that the upper portions of them shall be of much greater area than the lower. The upper leaf is also far larger than the lower, and turns in the direction of the stream; while the lower leaf turns against the stream, and overlaps the bottom edge of the upper leaf, and is forced against it by the pressure of the water. The comparative area of the leaves and position of the pivots is so arranged, that in ordinary states of the stream the tendency of the current to turn over the top leaf is counterbalanced by the pressure of the water against the overlap of the bottom one, the counteracting pressures keeping the weir vertical and the leaves closed, the water flowing as usual through a notch in the upper leaf. But when the water rises above the usual level, the pressure above, from greater surface and leverage, overcomes the resistance below, and the top leaf turns over, pushing back the lower leaf, and thereby offering the least possible obstruction to the water, and giving a passage at the very bottom of the stream to the gravel or mud.

The following diagrams will explain the construction of the weir:—

In answer to questions and objections, Mr. Bateman explained how difficulties, arising from trees floating down, the complete turning over of the leaves, &c., might be obviated by suitable stops, grating, &c.—Sir J. Robison observed, that the Rotterdam Canal had weirs on a similar principle; but Mr. Bateman explained that those weirs turned vertically on their axis. Mr. Vignoles stated, that from the cheapness and apparent advantages of this weir, he hoped it would be brought under the consideration of the Commissioners of the Shannon navigation, and recommended for trial on that river, to which it appeared peculiarly applicable.

Mr. Bateman, in obviating some difficulties suggested, explained that, in a weir 20 ft. long and 5 ft. deep, which his drawings and model might be supposed to represent, the sum of the closing pressures would be 7956 lb., and the sum of the opening pressures would be 7669 lb., the pivots being so placed as to give the areas of leaves above and below the lines of their axes the ratio of 2 to 1. The leaves would consequently be kept close by a force equal to the difference between these pressures; that is 287 lb. As the water rises these conditions would, however, be changed. Supposing the water to rise one foot, the additional pressure would be 1200 lb., of which 800 lb. would be exerted in opening, and 400 lb. in closing the leaves; and the result would be that the sum of the opening pressures would exceed that of the closing by 100 lb. The leaves would consequently be opened. He also explained that the sills against which the gates are made to close, might

be so regulated as to discharge the greatest flood of water without allowing the leaves to open more than a moderate quantity; but, if thought necessary, the gates ought to be allowed to assume a position perfectly horizontal in cases of high floods, and thereby oppose the least possible resistance to the passage of the water. The sluice might also be protected from being choked with trees and brushwood floating down the stream, by means of a grating.

Mr. Liddell read a paper on *Ventilation, on a method proposed by Mr. Fleming, of Glasgow*. It had been tried in a large building occupied by a number of poor persons, each family having a room. From the unclean and intemperate habits of the inmates, and their number (about 500), the house was very unhealthy, and many deaths from contagious diseases took place. In the plan adopted, the galleries were traversed by pipes of nine inches diameter, which united in a vertical pipe of large dimensions communicating with a lofty engine-house chimney; and small pipes of one inch diameter, at the top of each room, communicated with the pipes in the gallery. This plan had also been tried in the Glasgow Fever Hospital, in which the beds for fever patients, &c. were fitted up with the tubes for carrying away noxious effluvia. A similar plan for the ventilation of ships and steamers had been introduced by Dr. Reid, by leading tubes from the berths into a stove on deck, or, in steamers, into the chimney. Mr. Liddell stated that the expense for a house of 60,000 cubic feet was only 40 lb. of coal in twenty-four hours.

Sir J. Robison remarked, that from his experience the plan of Mr. Fleming, as far as regarded the size of the pipes, was inadequate.

ON THE ACTION OF LIGHTNING CONDUCTORS.

At the meeting of the Electrical Society on Tuesday evening, 19th July, a paper on this subject by Mr. Charles Walker, the Secretary, was read. The author entered into a very close investigation of the most important experiments that have been adduced in illustration of the nature of these instruments; and stated that discharges of Leyden batteries have been very generally selected as representatives of lightning flashes. He then showed the great difference between the visible character of the two flashes, and analyzed the cause on which each depends; demonstrating that the only case in which the resemblance is in any degree to be traced, is when a Leyden discharge fractures the glass, and passes directly between the coatings; and that in all other cases the said discharge is the result of two forces acting counter to each other. Thus he reaches his first conclusion, that the discharge of a Leyden jar does not resemble a flash of lightning; and therefore that Leyden jars should not be employed in these experiments. He then said that many points on which philosophers of the present day differ, are in connexion with the results of the Leyden experiments; and hence, if it can be shown that these experiments ought to be excluded, the at present complicated inquiry will be much simplified. He proceeded to trace the close resemblance between the discharge of a prime conductor and a cloud, illustrating his opinion by the aid of the magnificent machine belonging to the Polytechnic Institution; and showed that experiments with this conductor are in all essential points legitimate. He then described an extensive series of experiments to prove that a wire on which sparks are thrown from the prime conductor represents a lightning-rod; and then that sparks will pass from such a wire, and therefore from a lightning-rod, to vicinal conducting bodies. This last position was illustrated in a general manner by an assistant holding in his hand a glass rod surmounted by a brass ball; the ball was connected by stout wire with the gas-burners of the room, and thus when sparks were thrown on it from the conductor the electricity passed into a good discharging train to the earth. Now, while this took place, the application of a piece of metal to any part of the wire produced a spark; and not only so, but the same could be obtained from any of the gas-burners in any part of the room; and even when the writer descended into the workshops, two stories below the machine, sparks could be obtained from the burners there, which were indeed very much out of the direct line of circuit, so great is the desire of the electric current to use a wide path. This is the source of danger alluded to in the paper on Brixton church, reported in the last *Journal*. However, as the wires in this, as in several other similar experiments, were not directly between the conductor and the earth, the following arrangement was made, which answers every condition, and the general result of which proves that the wires above described do act as lightning-rods. Attached to the prime conductor of the machine was a thick brass rod, terminating in a five-inch ball; immediately beneath this was erected a similar rod surmounted by a ball. This rod was screwed into a small brass disc on the floor, and was considered a perfect representation of a lightning-rod, when sparks or flashes were passed into it. Near this a shorter and smaller rod (also terminating in a ball) was held; when the end of this rod touched the brass disc, no sparks passed between the two, when it did not touch, sparks passed in abundance. Much of the value of the inquiry was shown to depend on this experiment. If the former state of things represents what occurs in nature, there is no danger of a lateral spark; but if the latter, the danger is great. That metallic contact in this experiment prevented the appearance of sparks is an experimental proof of the safety resulting from the metallic connexions formerly recommended. These latter re-

suits are given in explanation of the well-known experiment of the two metallic discs; and Mr. Walker shows that no lateral discharge takes place between these discs, because the vicinal metal is in contact with the lower disc. While, therefore, the author agrees in recognising the value of lightning-rods, he has strong reason to believe that this lateral spark will occur unless proper precautions are taken; and though he differs in some degree from others, he does so in a feeling of perfect good-fellowship, and expresses a willingness to forsake his opinions whenever they are shown to be untenable. He states, in conclusion, that even if he is in error, still science will have gained something; for the received opinions will then have been able to withstand another assault, and will only stand the firmer.

IMPROVEMENTS IN LIVERPOOL.—ADVANCE OF ARCHITECTURE.

It has long been a subject of regret to men of refined and cultivated minds, that the architecture of our towns displays a miserable degeneracy from the purity of ancient taste. This degeneracy was perhaps to be expected. The state of the fine arts is determined by laws exactly the reverse of those which regulate the progress of the useful arts and mechanism. As, therefore, these have advanced, so has architecture declined. Elegance and chastity of design have been too often sacrificed to utility and economy; and the profession of the architect, which in Rome or Athens could claim the patronage of Augustus or Pericles, has in modern times received little encouragement from the great and powerful. But within these last few years a light seems to have been gradually dawning, which, we would fain hope, will reflect back something of the splendour of ancient days. Men of rank, of education, and refined taste, have applied themselves to a study which was before often degraded by the influence of ignorance and vulgarity. Architecture has rapidly advanced and a pure style is taking the place of a barbarous and confused medley of ancient and modern conceptions.

Perhaps our town of Liverpool is the best example we can bring forward to illustrate these remarks. The stranger must view with admiration, and our fellow-townsmen with pride, the taste and judgment displayed in the designs of many of our recent buildings. St. George's Hall and the New Collegiate Institution, for both of which we are indebted to the talent of Mr. Elmes, cannot receive too great commendation.

We purpose to furnish, from time to time, notices of the principal new buildings that may rise up amongst us, with a view to encourage the more general cultivation of a refined taste in Architecture, and shall on the present occasion commence with

BRUNSWICK BUILDINGS.

We have been much struck by a visit to this structure, now nearly completed, in Brunswick-street, and we are sure our readers will be gratified by a description of its chief characteristics. It has been constructed in the palatial style of Italian Architecture, presenting massive, unbroken façades towards Brunswick and Fenwick-streets; the rusticated basement is partially elevated above the street, and forms a substantial stylobate to the superstructure. The ground story is channeled between the windows, and surmounted by a Doric entablature, which runs entirely round the building, forming a band on which are set the windows of the first story; these windows are crowned with segmental pediments supported on appropriate trusses, whilst those on the story above have their pediments of the usual angular form. The main cornice, the most prominent feature in the design, projects three feet five inches from the face of the wall, and, in addition to the usual combination of mouldings, has modillions of a novel character; a frieze below is enriched with scrolls contained within panels. The quoins at each of the angles exhibit a variety in workmanship, and increase in solidity as they approach the ground. Throughout, simplicity appears to have been studied, and breadth of effect has been obtained, not so much by vertical breaks or superfluous ornament, as by adhering to what is termed "the horizontal line in architecture."

The entrances are in Brunswick-street, and form a centre-piece of three semicircular arches, filled in with bronzed perforated doors. One of which leads to a handsome court-yard. This court is entirely covered with glass, and affords light and access to the interior. The building is fitted up with sets of offices, arranged so as to meet the wants of every description of tenant, whose comforts appear to have been studied in every minute particular.

The whole building is of fine free-stone—that of the ground story of a light reddish tint, and all above it of white. Viewing both fronts from the opposite corner of Fenwick-street, a little higher up, it presents a very beautiful and striking appearance, from its general uniformity, or strict keeping in design, the richness of the cornicing and mouldings, and the chasteness of the ornaments—none of which are superfluously introduced. The great number of windows gives it also an air of liveliness rarely attained in commercial structures. Of these there are twenty-seven in three rows in the façade to Fenwick-street, which is the longest; and eighteen in that to Brunswick-street, in rows of seven in the two upper stories; and with four below—two on each side the two doors, between which is a handsome perforated window, making the apertures uniform in position. The arches over the doors and window between, we should add, have ornamental keystones carved in classical heads in full projection.

The covered court in the interior of the pile is an oblong square, with two ranges of galleries on each side, running longitudinally, and across the north end; and forming open and cheerful passages to the several offices above. These galleries are fronted with handsome massive balustrades or railings, each of a different but strictly classical design. The lower portion, or basement of the immense sky-light over head is of a segmental, or rather ogee form; and the centre is elevated some feet over the higher point of each segment, by light frame-work, which forms a continuous range all round of small perpendicular arched openings, affording ample ventilation. The sloping glazed roof on each side and at the ends (in pavilion form) overhangs this ornamental open-work—so that the rain cannot enter excepting in very high winds, and even then but slightly. There is an ornamental semi-circular projection at the south end of the court—within which is a spiral additional staircase. The appearance of this court, whether seen from below, or from any part of the galleries, is at once novel and palatial—the top resembling a conservatory. It is, indeed, a principal feature in the building, and has already attracted the attention and admiration of many visitors. The court, and the galleries, are smoothly covered with asphaltum, and the latter have numerous perforated gratings of cast-iron on the same level, admitting additional light and air. There is a range of offices, water-closets, &c., in the attic, all round the four sides of the base of the large sky-light covering the interior square or court, with a wide passage open to the air, and fenced off, clear of the glass, by a light iron railing. This passage forms a pleasing promenade. The rooms at this elevation are lighted both from the sides and by roof-lights, and a few creeping plants of slender foliage trained here and there to the glass, so as to subdue and mellow the light required for the rooms below, are alone wanted to give the whole the appearance of a green-house surrounded by cottages. It may be added, that the mode of ventilation is so well contrived, that no additional heat is perceptible in the area below, even while the summer sun is shining brightly.

The interior arrangements of the building appear to be such as to ensure the utmost convenience. The stairs are easy, and all the rooms well lighted and airy.

The town is indebted to Joseph C. Ewart, Esq., for this structure. He has evidently given to Messrs. Arthur and George Williams, his architects, more scope than is usually granted to men of their profession on similar occasions; and they appear to us to have displayed a rare degree of taste and judgment in the design and completion of the building, which may undoubtedly be considered an honour and an ornament to the town. It cost £13,000, and covers 835 superficial yards.

CHAPEL-STREET.

In Chapel Street, two fine commercial buildings are in a state of progress—one nearly completed, and the other (adjoining the property of Messrs. Waterhouse and Sons) raised to the plinth. The latter, at the corner of Chapel Street and west corner of Old Hall Street, is of large dimensions; and as it is situated immediately behind the Exchange Buildings, in the centre of the commercial portion of the town, and in one of its principal thoroughfares, public curiosity may be gratified by a sketch of the design. We have been kindly favoured with a sight of the plans and elevations, by the architect, Mr. Culshaw; and the following description (drawn up on the supposition that it were completed, which it will shortly be) will be found to be pretty accurate:—

The building is in the Roman style of architecture, and each façade (fronting Old Hall Street and Chapel Street, respectively) consists of an attached pilastade of the Corinthian order, from the temple of Jupiter Stator. It is mounted upon a rock-faced stylobate, crowned by a graceful attic, which dies into the pediment at the end. The principal façade, towards Old Hall Street, is pierced with six Venetian windows; and the end front, towards Chapel Street, contains three similar windows. These apertures are of large dimensions, being upwards of ten feet in width, and continued the whole height, from the basement to the entablature. They are each finished with an arch and an enriched key-stone, and are ornamented at the height of each floor with a neat panelled entablature, supported with light iron columns of the same order, set back from the face of the reveals. The space between the pilasters and windows are finished with sunk and channelled joints, which serve for the window dressings.

It is to be regretted that the corner of this noble building, at the junction of the two streets, is cut off at the height of the stylobate, for the purpose of public accommodation on the foot-walk; and this renders it necessary to introduce a truss to carry the angle pilaster, which produces a novel, but, we think, rather deteriorating appearance.

The interior arrangements are considered well adapted for the purpose for which they are intended—that of brokers' offices—the apartments being very roomy and well lighted.—*Liverpool Paper.*

FRESCO AND ENCAUSTIC PAINTING.

MR. SIMPSON, the decorator, of West Strand, has devoted considerable attention to the subject of fresco and encaustic painting, in consequence of the opinions expressed in their favour by the late Committee of the House of Commons, and the encouragement which they appear likely to meet with from the present Commission. He has made several experiments on various cements for the purpose of ascertaining their fitness as grounds for *opus*

mental and decorative paintings, and under the direction of Mr. Latilla and other artists has produced specimens of each. Mr. Simpson has, in some instances, adopted the ground of lime and marble dust, according to the plan of the ancients, on which he has succeeded in fixing the colours, and preserving their intensity and brilliancy so well that even a copious and repeated washing has not removed them, nor materially diminished their effect. Still, he has of course been confined, on this ground, to the use of such pigments as are not injured by lime. But the greatest success has attended the use of the beautifully white and hard cement, known as *Keene's cement*, as manufactured by Messrs. White and Sons of Millbank, on which, when in a moist state, the colours are easily applied, and become, when dry, perfectly fixed; and it possesses the farther great advantages of admitting of the highest degree of finish, and allowing the use of those pigments which will not bear the mixture of lime. These specimens have been repeatedly washed with soap and water. The painting in encaustic and a *tempora* (which Mr. Simpson has been enabled to render permanent) on Keene's cement, when dry and even polished, has proved quite satisfactory; as the brilliancy and clearness of the tints, contrasted and thrown out by the whiteness of the surface, produces an effect superior to any other ornamental painting yet attempted. No doubt other materials will be introduced, but it is those above described to which Mr. Simpson's attention has as yet been principally directed.

REMARKS ON THE "PONT DU CARROUSEL," PARIS.*

SIR—I beg to rectify an incorrect dimension contained in your number for July, relative to the size of the centre arch of the Pont du Carrousel in Paris, and will, with your permission, take advantage of this opportunity to offer some few observations on the construction of this bridge, erected by me, according to the plans of M. Polonceau, whose merit as an engineer of high standing is considerably enhanced by the conception of this very elegant structure.

The length of the chord line of the three arches is the same, viz., 156 ft. 6 in. intrados, and the rise or versed sine is 16 ft. English measure, being $\frac{1}{10}$ of the chord.

The arch is an arc of a circle, whose radius intrados is 198 ft. 5½, and focuses between the radii passing through the extremities of the chord line an angle of 46° 26'. The depth of the voussoir, or tubular rib, including the flanches, is 2 ft. 10½, and its breadth across the middle is equal to half its depth. Each tubular rib is composed of 23 pieces, having 11 lengths of about 14 ft. 9 in. on one side of the laminated wooden arc, whereas there are on the other side only 10 whole lengths and 2 half lengths, these half lengths being placed against the piers, in order to cross the joints so as to obtain greater rigidity, which by this combination became very considerable.

The wooden arc, which is composed of good, well seasoned fir, having been erected, greatly facilitated the work, for once cut to its proper shape, so as to leave a small space between the sides of the wood and the metal, the half voussoirs had only to be applied thereto, bolted together and forced up into their proper place by means of struts and wedges, after which keys were fitted into grooves reserved for the purpose at the extremity of each portion of the rib; and when all were ready they were gently forced down to a bearing, so as not to displace or deform the arc, beginning at the two piers, and terminating at the centre, where the last key tightened the whole; and so great was the power of these keys, that with a light hammer I could lift the whole arc from the struts, or lower it again with the greatest ease imaginable. These keys enabled us, therefore, to set the ribs with great precision, and almost simultaneously, which circumstance is of considerable importance in the construction of an iron bridge, on account of the inconvenient effect produced by expansion and contraction of the metal.

The hollow rib offers considerable advantage over the flat rib, on account of its rigidity, which is so great as to be capable of resisting all lateral strain with the aid of very little cross framing, or horizontal bracing.

There exists, in the construction of this bridge a peculiarity which has probably not been generally observed, although we were afraid, previous to the work being finished, that it would produce a very unpleasant effect. The evil was, however, unavoidable, as it arose from the circumstance that the Administration des Ponts et Chaussées required a certain height under the centre arch at high water, and the Prefet de la Seine would not on the other hand, consent to the elevation of the roadway on the quay above a certain height. It became, therefore, requisite to incline the chord line of the two side arches, and although there is in each a fall of 2 ft. 8 in. towards the quay, the effect is scarcely perceptible, unless when the water in the river rises nearly to the spring of the arch, which only takes place in the rainy season.

By the above plan the road over the bridge forms a curve instead of a level, and probably gave rise to the idea that the centre arch was of greater span than that of the other two. The curve of the road was still further increased, so as to obtain the level of the quay, by diminishing the diameter of the circular bearing rings against the buttress to 11 ft., whereas the diameter of those next the pier is 12 ft. 5½.

Great attention was paid to the form of section of the tubular rib, in order

to avoid any bad effect that might result from contraction in the casting, and such care was taken in moulding that very little remained to be done to the pieces when they came out of the sand. The tubular ribs were cast and faced at the Forges et Fonderies de Fourchambault, under the management of M. Emile Martin, who paid very particular attention both to the quality of metal employed, and to the moulding of the pieces.

The general allowance for contraction of cast iron in cooling is $\frac{1}{16}$, and this was found to be as near as possible the case. But the greatest difficulty to overcome was the tendency of these voussoirs to bend as they cooled, and that in consequence of the outer edges of the flanches cooling faster than the centre part, because it is well known that the slower the cooling process is carried on, the greater will be the contraction of the metal. To obviate this it was found requisite to curve the model itself about $\frac{3}{4}$ of an inch in the length of 14 ft. 9 in.

The circular rings and other cast iron pieces were cast partly in Paris, but the greatest portion in Normandy: with the exception of the facing of the voussoirs or tubular ribs, all the fitting-up was done on the spot.

The object of having these circular supports for the roadway was to obtain a certain degree of elasticity, sufficient to preserve the tubular ribs against the vibration of the road when carriages heavily laden are passing on the bridge; and this desideratum was most effectually attained, for I have frequently examined the effect, and have invariably found that when under the influence of a heavy load, and while the road was vibrating considerably, that, owing to the elasticity of these rings, the tubular ribs were perfectly steady. I shall be happy to add some further remarks on this subject, if you consider this paper to be worth inserting in your useful Journal.

I am, Sir,

Your obedient servant,

H. H. EDWARDS.

London, July 19, 1842.

[We shall, with much pleasure, receive any other communication Mr. Edwards may forward us.—EDITOR.]

MR. CHARLES WYE WILLIAMS' BOILER PROJECTS.

SIR—I have just been perusing a table of "Experiments on Furnaces and Steam Boilers," submitted by Mr. Charles Wye Williams to the British Association, and it is with unfeigned regret I observe the valuable time of the Association is occupied with such matter. The ostensible object of this table is to show the superiority of Mr. Williams's mode of effecting combustion over the plan usually adopted, but never was a table made less calculated to accomplish this object, and more likely to destroy the last vestige of professional confidence reposed in its author. The use of coal to steam engine boilers is the generation of steam, and I should imagine that even Mr. Williams himself cannot deny that that mode of combustion is the best which practically is found to generate the greatest quantity of steam with the least expence; and Mr. Williams may, when he first has leisure, begin to convince himself that he will not be benefitted by telling steam-vessel proprietors (to whom economy of fuel is of the greatest importance) that he has found a means of increasing the heat of flues, if he cannot also tell them that the consequence of such increase of heat is (and should not be) an increased evaporation of water by a given quantity of fuel. Mr. Williams, in his ten deductions from his two tables, has under consideration the quantity of water evaporated per unit of coal, economy of time, as he calls it, and the perfection of combustion. In his first deduction he says, that "the quantity of water evaporated by any given weight of fuel furnishes no test of the quantity evaporated in any given time." In the second, that "the quantity of water evaporated by each pound of coal is a very inadequate test of the quantity of heat given out by such coal." In the third, that "as the weight of water evaporated per pound of coal bears no proportion to the weight of water evaporated per hour, economy of fuel may be the reverse of economy of time." In the fourth, that "the area of the furnace has no necessary connexion with the heat generating power of the coal." In the seventh, that "the temperature of the products escaping by the chimney will be in the ratio of the heat in the flues, and both in the ratio of the rate of combustion and the quantity of heat generated," and so on through his other deductions. Now, in the name of all the smoke-preventing schemers of the present day, what has any one or all of these deductions to do with the superiority of Williams' furnace over the common one, if Mr. Williams can tell, I shall be much obliged to him, for so far as I can see, they are of use only in mistifying the subject, and enveloping it still more thickly in dense clouds of smoke. The mode of testing the economy of fuel with any kind of furnace or combustion, is of the simplest description, and to all schemers there is only one course open:—let them find how much water can be evaporated per unit of coal, used in the common way, with any boiler, and let them find how much fuel used in their way is required to evaporate the same quantity of water in the same time, with the same boiler unaltered, except in the furnace. Such is the way in which they will meet the case in practice, and such is the way in which they must treat it to procure the confidence of steam-vessel proprietors, and I may perhaps be allowed to add such is the way in which Mr. Williams' table does not treat it.

I am, Sir, your obedient servant,

A.

* Drawings of this bridge are given in the *Journal*, Vol. II. p. 79.

WOOD PAVING.

1. *On the Use of Mechanical Power in Draught on Turnpike Roads, with Reference to the new System of Wood Paving.* London: Blackwood, 1842.
2. *Wood Paving in London; a practical Treatise.* By J. LEE STEVENS. London: Spencer, 1841.
3. *Wood Paving in the Provinces.* By the same.
4. *Prospectus of the Marylebone Practical and Scientific Association for the Promotion of improved Street Paving.*

OUR earliest associations heretofore have taught us, in thinking of great roads as works of art, to esteem durability as their chief excellence, and a compact mass of stone as the best means of ensuring this attribute. Talk of engineering monuments, and the Appian Way rises before the mind's eye, or some of those many roads of the Romans which, after centuries of wear and tear, still bear on them the ever-flowing tide of traffic. And now this is to be as a dream; our ancient prepossessions in favour of stone or a macadamized concrete are to give way to what has been considered a most perishable material, one rejected in all structures in which the property of durability is to be consulted. We are not totally unacquainted with wooden roads, for the corduroy roads of America have made us familiar with them; but whatever our ideas may be of their capability of holding out against the ravages of time, we have too little liking for them, too little opinion of their comfort, to give them any chance of jolting our successors, when we are able to afford a more costly road. It is, nevertheless, true that the experience of two or three years has been sufficient to establish the efficiency of wood as a paving material, and to ensure it a large future extension.

Our prepossessions on the subject have been that wood as a paving material would be subject to great abrasion, would rapidly decay under the influence of weather, and would present a very slippery surface. The effect of damp upon wood, however, is rather paradoxical: if partially subjected to damp then decay ensues, but while kept constantly damp the injury is trifling. The abrasion experience has proved to be less than that of granite, while the practical operation, as we shall hereafter show, is such as allays all fears on that ground. As to the slipping of horses, the greater frequency of its occurrence upon wood paving is very questionable, while it is an evil which attaches only to a partial line of wood and stone paving, for were wood used on a large scale, an alteration in the shoes of horses, such as has been well provided by several inventions, would wholly remove this cause of objection.

Having, therefore, in wood a paving material of sufficient durability, whether we regard resistance to weather, or to abrasion from the weight carried on it, we have now to look at it in operation. In all specimens which have stood well we find an upper layer of wood reposing on a bed of concrete; for as to the idea of dispensing with the underlayer of concrete, it is one the fallacy of which has been shown and abandoned. The concrete we regard, therefore, as an essential feature of the system; and thus we have a non-elastic stratum of concrete with an elastic covering of wood, or a jacket, as it may be termed, in reference to its operations in defending the concrete from the weather, and a buffer, as repelling the shocks of the carriages traversing the road. Now it is in these elastic properties that, according to us, the whole secret of the success of wood-paving lies. Let us consider that there is not merely the road, which has to be provided for, but also the power which traverses it. Theoretically it might seem that the smoother and consequently the harder and more durable the road the better; but there is, as we have said, the power using the road to be taken into account, and the difference between an elastic and a non-elastic road is great in this respect. For as in the case of resistance to impact on the part of the non-elastic medium, the whole is distributed through the elastic medium of the power, so to speak, traversing the road, so, in the case of an elastic medium, this resistance is divided, and thus apparently diminished. Familiarly, this is illustrated by the example of wood and stone stairs: while we run up stone stairs our feet are pained, and we get sooner tired, to which the softness of the wooden stairs is an immediate relief. Therefore, upon the elastic medium we can do more work, either as to quantity or as to the length of time in which we are employed on it. This is the case with the horse: when it gets on the wood pavement the relief is sensible; instead of the whole resistance from the impact with the stone being communicated to its feet, as in the case of stone, it is distributed. If we consider the structure of the horse's leg, the natural habits of the animal, and the serious effect of a London pavement in shortening its working life, we must feel very sure that, on the ground of comfort to the

horse alone, the advantages of wood-paving are very great. Indeed, upon some lines of road, where there is much wood pavement, the sensible benefit to the omnibus and cab proprietors is acknowledged, and the extension of wood-paving must tend greatly to utilize the power of the horse, and so to reduce the price of his labour under every head, whether of length of life, of health, or of subsistence. Animate power is, nevertheless, not the sole power which we have to consider: a short space of time must bring the steam carriage also on the road, and we must provide for that. But the steam carriage is in a like manner provided with delicate and elastic machinery, and we know that the effects of vibrations on hard surfaces are greatly to increase the wear and tear and consequent expense of the machine. On this ground, therefore, the wood pavement is also to be preferred, in which respect many advocates of the steam carriage system have admitted the superiority of wood. So far, then, as to the mere effect of vibration on the elastic power employed, whether animate or inanimate; but in the case of animals, there is also a voluntary action which, although little regarded, is worthy of some attention. All those who attempt to estimate dynamically the results of muscular action, are well aware how much the will and disposition, the nervous condition of the animal, has to do with it, and under all circumstances, we should consider that wood would be more favourable to the exertion of the powers of the horse. What the seaman call "working with a will" is half the battle, and those who have noticed the wood pavement in Oxford-street must have seen the evident pleasure which the omnibus and cab horses have in running upon the easier surface.

In thus considering the tractive power we have perhaps travelled a little out of the logical order, for we should first have considered what is the quality of a wood surface with regard to the degree of resistance it affords to the traffic passing over it. We thought this, however, less important, for the capability of having tight joints is evident, and the smoothness of wood is one of the apparent objections to it. Presenting, therefore, an evident superiority over stone as to surface, the saving in wear and tear of carriages must be consequent. Attributing to wood that it causes much less wear and tear than stone to animals or vehicles passing over it, the converse of this is that those animals and vehicles must cause less wear and tear to the road, and, therefore, a very heavy item of expenditure be sensibly diminished, as also the amount of toll levied for the maintenance of the road. We may perhaps here mention that, according to Mr. Macneill's opinion, based on the relative wear of the iron of horses' shoes and of the tires of the wheels, that the wear and tear of horses' shoes and consequent destruction of the road is much greater than that of wheels, and the injury, consequently, of a steam carriage would be less than that of a coach and horses. While bringing in corollary opinions of this kind, we must not dismiss the question of elasticity without referring to the evidence of Mr. Macadam, as to the good effects of laying over a bog a Macadamized road on an underlayer of hurdles, which is the system of wood-paving reversed. It may, however, suggest some ideas.

As to the details of wood-paving, we are on the present occasion incurious about them, whether they ought to be cubes or hexagons, or what, provided always that they are laid upon a solid substratum. The mode in which the blocks are laid, as to the grain of the wood, is important to be considered, whether with the fibres vertically, horizontally, or diagonally. This is a subject well worthy of experiment, first in relation to the mechanical strength, then as to abrasion of surface, and further as to the beneficial effect or otherwise of the admission of damp by the fibres. Another subject for experiment is as to the durability of wood under several circumstances: first, under alternate wetness and dryness, and secondly, while in such condition, as to the effect of frequent traffic or otherwise. It appears at present that, while bearing considerable traffic, wood will stand exposure to all weathers; while in many other circumstances seemingly more favourable, it is attacked with rot. The cause of this has never been satisfactorily ascertained; but it remains as the subject of experiment, like the anomalies in iron rails, where, side by side, will be found rusty rails and bright ones, under nearly the same circumstances.

Looking at wood-paving in its various relations, we come to another topic—the convenience to the public from the sound of the wheels being deadened on the wood pavement. The greater quiet which ensues is much appreciated by the shopkeepers and other residents in large thoroughfares; but the convenience is not less to the passengers. Those on the footway and those in carriages, besides having freedom from noise, which is a great relief to many, are enabled to converse, which at present, in Cheapside or the Strand, is often impossible. It is on this ground of greater quiet that wood-paving has been already adopted around many churches and public buildings, and its extended use for this purpose will not only benefit the auditories but also the

public, whose progress through the thoroughfares on Sundays is greatly impeded by the barriers placed for diverting the carriages from places of worship. Around the New Church in the Strand, at St. Giles's, the Old Bailey, and many other places, wood-paving has been successfully used, and we hope it will be even more extensively adopted. Cleanliness is another requisite of public accommodation, which is a recommendation of wood-paving.

On the ground of economy, the first cost of wood-paving, taken in conjunction with the outlay for repairs, successfully bears the comparison with granite or macadamized roads, while the economical advantage in the wear and tear of horses and vehicles is still greater.

Wood-paving has now been pretty extensively adopted in the metropolis, and a good part of the line from the Mansion House by Oxford-street to Regent-street, and by the Strand to Westminster Bridge, is laid with it, and these several portions we hope to see united, so that it may be tried upon a more satisfactory scale than has yet been done. Not that we have any distrust as to it, but because we think that scope has not yet been afforded for the full display of its good qualities. While on this subject we may mention, incidentally, that Mr. Bradwell, the machinist of Covent Garden Theatre, the inventor of the artificial ice laid down in Baker Street, in the New Road, and in the Colosseum, in 1835 submitted to the City Paving Commissioners, a system of wood-paving, similar to that afterwards laid down in the Haymarket, but the idea of wood was scouted by the Commissioners.

Now let us turn to the first work with the title of which we have headed this article. It is devoted to the advocacy of the steam carriage system, as the best means of effecting which it maintains that it is requisite to pave the turnpike roads with wood. According to the author, and to Mr. Worsley, one of the steam carriage inventors, in a pamphlet published by him, "the only real difficulty at present to the general use of the steam carriage instead of horse power arises from the great inequalities of surface resistance on the common roads." These inequalities of surface resistance are said in some cases to require an 8-horse, in others perhaps a 40-horse power, "arising from the softness rather than the roughness of ordinary roads, which are formed of materials varying in nature and quality, liable to be affected by every change of atmosphere." The remedy for this is said to be found in wood-paving, as it presents the same firm and even surface in all seasons and weathers. It is recommended, therefore, to wood-pave all the turnpike roads, when the superior economy and speed of the steam carriage over horse power will, it is expected, be brought to bear.

Mr. Stevens is the agent and professed advocate of the Metropolitan Wood Pavement Company, the most successful company hitherto, and of course his strain is all leather. The author of the first pamphlet has also a preference for this company, but his reasoning is general.

The contest in the Marylebone Vestry on the question of paving Oxford-street with wood was conducted with great acrimony, and with a spirit of partizanship such as to disgust all well-thinking men. When, therefore, this matter was decided by the triumph of the wood-paving party, sober consideration as to the importance of paving as an item of municipal expenditure, and the expediency of economizing under this head, led to the novel circumstance of a local society being founded for the promotion of improved street-paving, which has been organized, and we hope will be successful in its exertions. Unpledged to any particular system, whether of wood, of stone, or of granite, the object of the supporters of this institution is to point out to their fellow-parishioners the best mode by which paving can be effected, and the funds of the parish economized. It is, in fact, a local association for carrying out similar objects to those of the Metropolitan Improvement Society, but in a more restricted way. When we consider the large amount of local taxation in this country, direct and indirect, scarcely under ten millions, in the shape of poor rates, county, church, highway, paving, sewer, and lighting rates, and turnpike tolls, the class of persons by whom these sums are expended, and their woful ignorance of their duties, with its attendant prejudices—the Poor Law for example—we may feel fully assured that a very large amount of money is wasted which has been already raised in ways oppressive to the community. The necessity, consequently, of public enlightenment on municipal administration is very great, and no better means exist for the attainment of this object than the formation of local societies like the Marylebone Street Paving Association. A less expenditure is not always the cheapest mode of administration, while mechanical circumstances will often impede the best-intentioned but uninstructed administration. One parish in London lost several hundreds a year by using dirty scales in the workhouse; others have suffered by receiving hot bread instead of cold, bread losing often as much as five per cent. in cooling, a difference pocketed by the contractor. It is by intimate acquaintance with details,

therefore, and not by party wrangling, that the public funds are to be saved, and it is highly desirable that the well-instructed and independent members of the community should bear this in view. To Mr. Charles Cochrane, the founder of this Association, we think great praise is due. Being a member of the Marylebone Vestry at the time of the above-mentioned Oxford-street discussion, he employed himself zealously in collecting all the evidence he could as to the durability of wood in various positions, the results of which investigations he detailed in his speeches to the vestry. In deciding the opinion of the vestry in favour of wood-paving his exertions had great weight, and subsequently as a permanent means of benefiting the parish he established the Association in question. Independent in his social position, of large fortune, unbiassed in favour of any particular plan, the motives of Mr. Cochrane cannot be impugned, and he may rest assured that by the example he has afforded, which will have its weight in other places, as well as by the good he has effected, he has conferred a greater benefit than if he had availed himself of his standing for those party and political purposes which are so much more tempting. Had he obtained a triumph for blue or yellow, had he turned out the functionary of one party to put in the nominee of another, he might have ensured greater applause from his constituents, but he would not have done so much good. We cannot impress too much on all parties the propriety of giving up party warfare where local interests are involved, requiring the most prudent and careful consideration.

In conclusion we strongly recommend all public bodies who are about to adopt wood-paving, to take the precaution of having a good bed of concrete, of Thames sand and stone lime, with a small portion of Roman cement and puzzolana. As to wood without concrete, it is quackery, and a waste of money.

SCULPTURE IN ARCHITECTURAL DESIGN.

(From the *Athenæum*.)

If in one of its shapes, the spirit of calculation has been prejudicial to architecture in this country, it has, in another, occasionally been rather favourable to it, and given it an impulse. While it has prevented many of our public structures from being what they ought to have been, causing them to be turned out of hand maimed, hurried off, unfinished productions; it has sometimes, in the case of private speculations, led to a degree of architectural display that contrasts forcibly with the grudging penuriousness which has hitherto been allowed to *manifest* itself so offensively in works of greater importance—those from which our taste as a people is likely to be judged by other countries. On examining the numerous public structures erected within the last five-and-twenty or thirty years, we find quite as much cause for regret as for congratulation—for regret that so little should have been made of the respective opportunities afforded; and that, too, not so much in consequence of economy, as from want of judgment and taste; and owing to the designs not being properly matured—to their not being purged from inconsistencies—and to there being a more or less offensive disproportion between the character aimed at and the mode in which it has been carried out. Nor can we refrain from here remarking, that while architects lay so much stress on the proportions of the orders, &c., which are only matters of mechanical routine, easy enough to be learned even by the dullest, few of them pay attention to what may be called *artistical proportion*—to that of the *ensemble*, so that this last shall be in perfect "keeping," and homogeneous in character, instead of looking, as is too frequently the case, no better than a compilation of ill-assorted fragments, where pretension and meanness go hand in hand. The list of *lost opportunities* would be one of some extent; and we should certainly place in it more than one structure or architectural improvement, which less fastidious and less *exigant* or more good-natured critics have not scrupled to commend. Buckingham Palace, the Post Office, British Museum, Mint, College of Physicians, York Column, Covent Garden Market, King's College, the Cemetery at Earl's Court, and numbers numberless would be so classed by us, notwithstanding that it is not difficult to point out in every one of them some individual merit—some solitary feature, perhaps quite an accidental one—for which it may be praised, if we choose to shut our eyes to the solecisms and sins by which it is overwhelmed—to the frigid dullness and insipidity, or vulgar taste and architectural bathos manifested in each of them as a whole. It avails not to say, that in many instances the architect has not fair play, that sufficient means are not afforded to enable him to do all he could wish; because it behoves him to display his ability by making the most of the means which are afforded him, instead of injudiciously aiming at more than, as he must or ought to be aware

he can at all satisfactorily accomplish. If architects are so pinched by their employers that they cannot finish up their buildings consistently, why, in the name of common sense, do they squander away so great a part of their pecuniary resources upon such extraneous common places as columns and pilasters, dragged in for the nonce, as if for the express purpose of making the poverty of the rest of the building all the more apparent and offensive; and in such manner as to bring columns and porticos now almost into disrepute? Such a system is no less at variance with economy than with good taste; and has served only to fill the land with buildings in a pseudo-Grecian style, marked by an offensive mixture of showiness and poverty—with what is, in fact, hardly worthy of the name of style at all, it amounting to no more than feeble, mechanical mannerism. Private speculation has, on the other hand, occasionally encouraged architectural design on a scale of liberality that contrasts forcibly with the petty parsimony observable in buildings of a higher grade, and where it becomes positively offensive. The shop architecture of the metropolis has improved, although by no means in the degree that could be wished; since, for the greater part, it exhibits more of expensive showiness than of either good taste or invention. The individual architectural specimens of this class, which deserve to be pointed out, are comparatively few; for when we have mentioned one at the corner of the Quadrant, opposite the County Fire Office, at the corner of Oxford Street and Berners Street, another by Mr. Inwood, in Old Bond Street, a fourth in Tavistock Place, by Mr. Maddox, and one just opened in Aldgate—which last is a more striking façade of its kind than, perhaps, any other in town—we have enumerated nearly all that are remarkable for more than the superficies of plate glass. There is, however, one piece of architecture which, though it does not exactly answer to the name of *shop*, belongs to the same caste, and which certainly may be referred to with approbation; we mean that called the Kemble Tavern, at the corner of Bow Street and Long Acre. Notwithstanding that it is executed merely in *compo*, and that it is now barbarously disfigured and vulgarized by certain very unclassical insignia of the business to which it is devoted; in point of design this building puts to shame many which are constructed of far more durable material—some of them, too, by men of eminence in their profession—persons who would, doubtless, stand amazed, if asked to make a design for a similar purpose. When we look at the two new Assurance Offices in Bartholomew Lane, at the “Atlas” in Cheapside, or the “Westminster and British” in the Strand, we feel not only dissatisfied, but convinced, that the architect of the Kemble Tavern would have acquitted himself far better, and made much more of them, had the opportunities been afforded him: in saying which we are at any rate unprejudiced, for of the individual we know nothing whatever, but form our opinion solely from that sample of ability and taste. He certainly has shown more than ordinary *gusto* in that little production, which, though not quite so celebrated, is, we venture to affirm, a better piece of design than Palladio's House at Vicenza. He—that is, the Bow Street, not the wonderful Vicentine architect—has there introduced some novel and pleasing ideas, and in adopting the Tivoli example of the Corinthian, he has not, as some others have done, omitted what is so strikingly characteristic in the original, namely, the “bossy sculpture” of the frieze, deprived of which the whole is thrown out of keeping, and the entablature no longer agrees with the columns. At the same time we must admit that he has, in one respect, deviated both from the character of the order, and from that of the rest of his own design, inasmuch as he has made the *antre-caps* by far too plain, so that they contrast disagreeably both with the entablature and the capital of the columns themselves; which is, in our eyes, a greater blemish than the accidental disfigurement we have alluded to.

Among other architectural speculations belonging to the *genus* “shop,” we have the Pantheon Bazaar and the Lower Arcade, either of which might almost satisfy the most *Pennantizing* antiquary for the loss of old Exeter Change. As a speculation, it may be doubted whether the “Arcade” has answered; neither does it seem to have conferred any reputation upon the artist who designed it; yet it is, nevertheless, a tasteful and scenic *merceria*, and is, besides, admirably accommodated to a climate like ours.*

* We have just heard that a similar *passage*, as the French call it, is about to be formed, extending from Wellington Street North, facing the English Opera House, to Catherine Street. The situation does not promise much for the scheme, because no additional communication or thoroughfare in that direction seems to be required; whereas it would be a great public improvement could some of the narrow lanes and alleys, in different parts of the town, be converted into well-paved covered passages, so as to be cool in summer, and clean and dry in wet weather.

APPARATUS FOR REVERSING ENGINES.

SIR—Having seen in your valuable Journal a description of a method for reversing engines, by the use of the common side valve, making the induction and eduction pipes alternately steam pipes, I submit to your notice a method of accomplishing the same in a much more simple manner, as will be seen on reference to the accompanying diagram, and shall feel obliged by your giving it a place in your forthcoming number.

Fig. 1.

Figure 1 represents the section of a cylinder and nozzle of the form generally used, with the addition of a valve for reversing, made with two pistons to obviate the pressure attendant on the use of the slide valve—the pressure on the pistons being the same on both ends.

Figure 2 is a horizontal section of the same.

Figure 3 is a section of the valve for reversing; C passage to condenser; S steam pipe; A and B passages leading to nozzle. The letters are the same in all the diagrams.

Fig. 2.

Fig. 3.

In the position of the valve as shown, the steam is admitted through S, passing through A into the cylinder, forcing the piston P up. If it is wished to reverse the engine, we have only to move the piston valves to E E, as shown; the steam being admitted through S, as before, passes through B B to the top of the piston P, and forces it down. The slide valve will have to be made with no lap, and must be worked by an eccentric keyed on the shaft.

In large engines where expansion valves are used, they could be set so as to cut off the steam to the end of the stroke, as the slide valve would be open to the full length of the stroke. The piston valves would also act as a throttle valve, and could be worked easily

by one man in a pair of large engines, whereas by using the slide itself four or six would be required. This would, I should think, add greatly to its efficacy by being so easily under control—more especially in the Thames and the Clyde, in the latter of which it is often necessary to stop and reverse every two or three minutes.

May 17, 1842.

SETTON.

P.S.—Lap is not applicable to a valve to be worked by an eccentric keyed on the shaft to work the engine both ways, for if it was set right for going a-head, it would be too late to reverse.

[We think very favourably of the plan for reversing engines communicated by our correspondent. In large engines its employment might supersede the necessity of throwing the engine out of gear, and the use of starting apparatus, and would confer a facility in starting and reversing which does not at present exist. We do not understand what our correspondent means by cutting off steam to the end of the stroke. The expression seems to us to involve a contradiction, inasmuch as the act of cutting off means the prevention of more steam entering the cylinder at some point of the piston's progress before the stroke is completed. We may further observe that although it is quite true that lap is inapplicable to a fixed eccentric intended to move the engines both ways, it is not inapplicable to a fixed eccentric in ordinary engines, for in ordinary engines no fixed eccentric can move the engines both ways. Lap is only inapplicable in the case of some double-ended levers, or in the mode of reversing our correspondent recommends.—EDITOR.]

STEAM NAVIGATION.

THE "ATMOSPHERIC" STEAM-BOAT.

THIS vessel is adapted for river navigation, the hull is entirely of iron, but with deck and fittings of timber. She was built by Messrs. Ditchburn and Mair, the eminent iron boat builders of Blackwall.

The length between perpendiculars is 150 ft.; breadth of beam, 18 ft.; depth of hold, 9 ft. 9 in.; and draught of water, 4 ft. 8 in.

The engines were constructed by Messrs. John and Samuel Seaward and Capel—they are upon the old atmospheric principle. There are three cylinders placed immediately under the line of shafts, with the cranks set at an angle of 120 degrees, so that in every portion there is the full power of one cylinder in action, which produces an equable and uniform motion. There are no cylinder covers or piston rods, as the connecting rods communicate at once from the pistons to the cranks. The pistons are forced upwards by the pressure of the steam, and then allowed to descend again by the production of a vacuum underneath, the air constantly pressing upon the upper side. There is one condenser and one air-pump connected with the three cylinders.

The engines have been worked several times, and are represented to have performed most admirably and efficiently, and the boat proved to be of unrivalled speed.

The following are the proportions of the engines:—the cylinders 47 in. diameter, and 3 ft. stroke; the pistons make 34 strokes per minute; the pressure of the steam is represented to be 8 lb. on the square inch; the paddle-wheels are 16 ft. diameter, and have 24 boards, 9 ft. long by 14 in. deep.

The power of the engine may be calculated thus:—if we take the pressure of steam in the upward stroke at 6 lb., and the pressure of the atmosphere occasioned by a vacuum underneath the piston, on the downward stroke at 13 lb., allowing a trifle under the full weight of the atmosphere,

we shall have a mean pressure of $\frac{6+13}{2} = 9.5$ lb. on the upward and down-

ward stroke; and the velocity of the piston (3 ft. x 34 x 2) = 204 ft. per minute; and the area of each cylinder ($47^2 \times .785$) = 1735 in.; we shall have

for the power of the 3 cylinders $\left(3 \frac{9.5 \times 1735 \times 240}{33,000} \right) = 306$ horses nearly.

And if we take the same proportion of nominal power to the effective power as in the ordinary low pressure marine engine, which is generally half, we shall have the nominal power of the three cylinders = 153 horses, which it must be admitted is a tremendous power for so small a vessel. We cannot, therefore, be surprised that the boat is one of the fastest, if not the fastest on the river.

We are at a loss to conceive what advantage Messrs. Seaward and Capel expect to gain by the revival of the atmospheric engine for navigation purposes, except it be to get a longer stroke in applying the direct action principle. Against this we have double the capacity of steam cylinders, consequently nearly if not quite double the weight and expense, besides the very serious evil of exposing the interior of the cylinder at every downward stroke to the cooling influence of the atmosphere.

To show that the cylinders are double the capacity of those constructed on the ordinary principle, let us take the pressure of the steam as above at 6 lb., and the vacuum equal to 13 lb., which together is 19 lb., just double, at each upward and downward stroke; at the mean pressure taken in the above calculation, therefore, one half the capacity of cylinder will be sufficient. Again, let us prove this more clearly, by calculating the power of two cylinders working on the ordinary reciprocating principle, each $40\frac{1}{2}$ diameter; the area of the two being 2600 inches, rather less than half the collective area (5205 in.) of the atmospheric cylinders, the power will be, taking the same stroke and velocity as before, and pressure (6 + 13) = 19 lb.,

$\left(\frac{19 \times 2600 \times 24}{33,000} \right) = 305$ horses.

The Steam Association.—We must honestly confess that the Steam Association has disappointed our hopes, in common with most persons interested in the advancement of the art of steam navigation. Not that we have any fault to find with anything the Association has done—all of which is useful in its kind, and in our eyes has been wisely planned and ably prosecuted—but that many things have been left unattempted of far greater moment than any of those to which attention has been given, and which the Association and it alone is competent to undertake. What, for example, can be of greater importance than the establishment of a system of registration, such as that in use in Cornwall, of the consumption of fuel in different steam vessels, in relation to the power exerted; and who but the Steam Association could establish such a system? The duty of the Cornish engines has by this simple expedient been raised in the course of a few years from 26 millions of pounds raised one foot high, by a bushel or 84 lb. of coal to 120 millions—an increase of mechanical virtue of nearly 5 times, simply in consequence of the care and emulation the system of registration has excited. It would be too much perhaps to expect an equal increase of efficacy, or equal diminution of expense in steam vessels, but that great improvement would be effected by registration is scarcely to be doubted; and as it is the propelling power which constitutes the great expense in the maintenance of steam vessels, we think the attention of the Steam Association should first be given to that subject, and that the discussion of pilotage laws, harbour duties, &c.—which, however settled, can effect steam interests little in comparison with the economization of fuel—might be wisely postponed until a system of registration has first been organized. We refrain from going into any details relative to this question for the present, and must be content with saying that in our apprehension the details do not involve any practical difficulty or inconvenience. We trust the Association will speedily give its attention to this subject, and will use its best efforts to assist or facilitate the accumulation of all statistics of steam machinery that appear calculated to advance steam navigation, and promote the interests of those engaged in it. Hitherto the Association has been the representative, not of all the considerations proper to steam enterprise, but of those only which have a commercial complexion, and which any association can do the least to ameliorate. It does not augur well to see our engineers and ship-builders present only at the annual dinners; but we trust to see them soon taking a part in the Association's proceedings, and to see the Association assume its proper position—not of the representative of the counting-house—but of the representative of the science.

The Locomotive, No. 1.—A boat with this cognomen is now running between the Adelphi Pier and Greenwich. She is fitted by Messrs. Braithwaite, Milner and Co. with a locomotive engine precisely the same as those working on railways, with the exception that it is taken off its wheels, and set upon bearers laid across the bottom of the boat, and instead of the railway wheels there are fixed upon each end of the driving or cranked axle a pinion wheel, 2 ft. 4 in. diameter, which works into a cog wheel 7 ft. diameter, keyed on to the shaft of the paddle-wheels; the shaft is in one piece, and has a bearing in the centre upon the top of the boiler. The engine is what is generally termed a 10-ton engine, fitted with two cylinders, 12 in. diameter, and 18 in. stroke; the pistons make 100 to 130 strokes per minute. The boiler is 3 ft. 2 in. diameter, and contains 84 tubes 2 in. diameter and 8 ft. 6 in. long, and a circular fire box, 3 ft. 3 in. diameter. The pressure of the steam within the boiler is from 45 lb. to 50 lb. on the square inch. The paddle wheels are 11 ft. 4 in. diameter, with float board 10 in. deep, and 5 ft. long. They have a dip of about 18 in., and when the engine makes 100 strokes per minute the paddle-wheels make 33 revolutions. The length of the boat, which is iron, is 103 ft. on the water-line, with a beam of 11 ft. 6 in., and draws 2 ft. 2 in. when light. The total weight of engine, boiler, paddle-wheels, and coal boxes, is 12 tons; the engine room occupies 21 ft. in length of the boat.

The speed is equal to about 12 miles through the water; and the consumption of fuel is about the same as on railways. In consequence of the engine being fixed in the boat instead of moving at such high velocities it does on the rails, there is nothing like the same wear, or so much liability to derangement. There are one or two evils attendant upon the present use of the locomotive engine; one is, that in consequence of the muddy state of the water of the river Thames, the boiler is apt to *prime*, which may be obviated by making a larger steam chest than ordinary; there is also an unpleasant horizontal vibratory motion in the boat, in consequence of the horizontal and rapid movement of the pistons, which we think can be got rid of by placing the cylinders diagonally on the sides of the boiler. This alteration would also allow the moving parts to be got at much better than they now are, which, in consequence of being placed under the boiler, are very awkward to be got at. No doubt these defects will be easily got rid of, and other improvements introduced, under the able hands of Messrs. Braithwaite, Milner, and Co.

MISCELLANEA.

In last month's *Journal* we gave an account of the removal and shipment of the immense block of Granton stone presented by his Grace the Duke of Buccleuch for the statue of the immortal Nelson, and which is intended to grace the summit of the column now erecting in Trafalgar-square by Messrs. Grissell and Peto; we have now to record its arrival into the river Thames, and removal to Trafalgar-square. On Saturday, June 25, it was safely landed at Mr. Foote's wharf, Abingdon-street, Westminster, in the presence of a large number of spectators, and was conveyed by the aid of 22 horses through Parliament-street and Whitehall to its last and final resting-place, Trafalgar-square. The crane by which this ponderous mass was landed was erected about three years since, by Mr. Luke Embleton, of Southwark, under the superintendence of Mr. Thomas Searle, of Wapping Wall, and is a beautiful piece of mechanism. The work, however, of its elevation to the top of the column still remains to be effected, and we hope its accomplishment will be as successful as its journey hitherto. The stone in question is stated to weigh 30 tons, and has already been reduced to favour its more easy removal from a block weighing at least 45 tons; it is of the description known as "Craig-leith," of the liver rock, and in point of durability equal to granite. We understand that the removal of this stone from the neighbourhood of Edinburgh to Charing-cross has been effected without either the breaking of a chain, or the splintering of a handspike. Mr. Bailie, the sculptor, has now his part to perform.

Claudet's Daguerrotypes.—We were much delighted to witness at the Adelaide Gallery M. Claudet's instantaneous process of taking portraits. To him is due an improvement which, we may say, is almost equal to the original discovery. Previously to this improvement, there was considerable difficulty in obtaining a faithful likeness, in consequence of the time required for a sitting, and also the necessity for having a clear sunny day for the operation; but now, in a strong light, it will require but a moment or two, and even on a cloudy day, as it was when we last witnessed it, portraits can be taken in from 10 to 14 seconds. To show the instantaneousness of the process, M. Claudet is enabled to take portraits of animals, trees, plants, &c. He has also introduced another important improvement—that of introducing a back ground, representing a landscape or interior. During the last month M. Claudet was honoured with a visit from the Queen Dowager, who had her portrait taken as well as of those of the suite who attended her. With these she was highly delighted, and expressed her astonishment at the rapidity of the process. We wish we could see this valuable process more extensively employed in obtaining copies of some of our finest specimens of sculpture, paintings, and public buildings. Although M. Claudet at first devoted his attention with much praiseworthy effect in obtaining portraits, if we may use the term, of all the principal buildings in London, Paris, and Italy, he met with little or no encouragement. He was, therefore, obliged to devote his attention to a more profitable department—that of human portraiture, and, if we judge rightly from the number of persons who daily flock to his studio at the Adelaide Gallery, he will find it amply enrich his coffers, and make up for his previous losses. We with much pleasure recommend a visit to his establishment where may be seen portraits of many public characters, and of many celebrated buildings.

Asphalte Roofing.—It was remarked as a singular circumstance, during the conflagration at Hamburg, that roofs covered with asphalte, of which there are some here, opposed rather than encouraged the progress of the flames. It was imagined, on account of the substance of which these roofs were composed, that they would easily catch fire, and be the cause of great mischief; such, however, was not the case, for it appears that the fire had little or no effect on them: and when the roofs of the houses fell in, the asphalte, in which a sort of rubble is mixed up, was found to have resisted the effects of the heat, and like a mass of dirt, served rather to smother the flames than to give them increased vitality.—*Times*.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 6TH TO 28TH JULY, 1842.

Six Months allowed for Enrolment, unless otherwise expressed.

JOHN HARRISON SCOTT, of Somers Town, engineer, for "improvements in metal pipes, and in the manufacture thereof."—Sealed July 6.

GEORGE EDMUND DONISTHORPE, of Bradford, Yorkshire, top manufacturer, for "improvements in combing and drawing wool, and certain descriptions of hair."—July 6.

JOSEPH HALL, of Cambridge, agricultural implement maker, for "improvements in machinery for tilling land."—July 6.

LADY ANN VAVASOUR, of Melbourne Hall, Yorkshire, for "improvements in machinery for tilling land."—July 7.

RICHARD HODGSON, of Montague-place, in the county of Middlesex, gent., for "improvements in obtaining images on metallic and other surfaces."—July 7.

JAMES TIMMINS CHANCE, of Birmingham, glass manufacturer, for "improvements in the manufacture of glass."—July 7.

CHARLES AUGUSTUS PRELLER, of Eastcheap, merchant, for "improvements in machinery for preparing, combing, and drawing wool and goat's hair." A communication.—July 7.

WILLIAM FAIRBAIRN, of Manchester, engineer, for "improvements in the construction of metal ships, boats, and other vessels, and in the preparation of metal plates to be used therein."—July 7.

JOHN PERRING, of Cecil House, Strand, hat manufacturer, for "improvements in wood paving."—July 7.

JOHN BIRD, of Manchester, machinist, for "improvements in machinery or apparatus for raising or forcing water and other fluids, which said improvements are also applicable as an engine, to be worked by steam, for propelling vessels and other purposes."—July 7.

WILLIAM PRITCHARD, the elder, of Burley Mills, Leeds, manufacturer for "an improved method of consuming or preventing smoke, and economising fuel in steam-engine and other furnaces."—July 7.

WILLIAM REVELL VIGERS, of Russell-square, Esq., for "a mode of keeping the air in confined places in a pure or respirable state, to enable persons to remain or work under water and other places, without a constant supply of fresh atmospheric air." A communication.—July 7.

JEAN BAPTISTE FRANCOIS JOUANNIN, of Upper Ebury-street, Pimlico, mechanic, for "improvements in apparatus for regulating the speed of steam, air, or water engines." A communication.—July 9.

JOHN PETER BOOTH, of the city of Cork, merchant, for "improvements in machinery and apparatus for working in mines, which are applicable to raising, lowering, and transporting of heavy bodies; and also affording assistance in promoting a more perfect ventilation of the mine."—July 9.

JAMES CRUTCHETT, of William-street, Regent's park, engineer, for "improvements in manufacturing gas, and in apparatus for consuming gas."—July 12.

THOMAS DEAKIN, of Sheffield, merchant, for "improvements in the manufacture of parts of harness and saddlery furniture."—July 12.

JEAN LEANDRE CLEMENT, of St. Martin's-lane, engineer, for "improvements in apparatus for ascertaining the temperature of fluids, and also the pressure of steam."—July 12.

WILLIAM HENRY STUCKEY, of St. Petersburg, now of Upper North-place, Esq., for "a pneumatic engine for producing motive power."—July 12.

JOSEPH SCHLESINGER, of Birmingham, manufacturer, for "improvements in ink-stands, and in instruments for filing or holding papers and other articles."—July 16.

ROBERT BENTON, of Birmingham, land agent, for "improvements in propelling, retarding, and stopping carriages on railroads."—July 16.

JOSEPH BARLING, of High-street, Maidstone, watch-maker, for "improvements for producing rotary motion in machinery, worked by manual labour."—July 16.

JOHN CHATWIN, of Birmingham, button manufacturer, for "improvements in the manufacture of covered buttons."—July 16.

CHARLES ROBERT AYERS, of John-street, Berkley-square, architect, for "improvements in ornamenting and colouring glass, earthenware, porcelain, and metals."—July 23.

JOSEPH PARTRIDGE, of Bowbridge, near Stroud, Gloucester, dyer, for "improvements in cleansing wools."—July 23.

EUGENE DE VARROC, of Bryanstone-street, Portman-square, gent., for "apparatus to be applied to chimneys to prevent their taking fire, and for rendering sweeping of chimneys unnecessary."—July 23.

ALEXANDER JOHNSTON, of Hill House, Edinburgh, Esq., for "improvements in carriages, which may also be applied to ships, boats, and other purposes where locomotion is required."—July 23.

EDWARD COBBOLD, of Melford, in the county of Suffolk, Master of Arts, clerk, for "improvements in the means of supporting, sustaining, and propelling human and other bodies on and in the water."—July 28.

TO CORRESPONDENTS.

"C. B."—We cannot give any particulars at present of the progress of the large iron steam vessel at Bristol; we will try to do so the first opportunity.

We very much regret to be compelled to decline inserting Mr. Tott's comments on our criticisms in last month's *Journal*, for if we do so, we should then have similar comments from all other parties who may not like our notices of their productions.

Mr. Shuttleworth's Pamphlet on Hydraulic Propulsion on Railways must stand over for further consideration.

Books received and not noticed in the present *Journal*:—"Hand-Book of Manchester;" "On the Exaporative Power of Boilers, by C. W. Williams, Esq."

ERRATA.—In the Review of Mr. Booth's pamphlet, p. 257, in the fourth paragraph, lines 6 and 10, for two feet, read four feet.

EXPERIMENTS ON THE TENACITY OF WROUGHT IRON,

By JAMES NASMYTH, C.E.

It may perhaps be interesting to some of the readers of your *Journal* to have an account of the results of some experiments which I have lately been making, with a view to obtain more correct knowledge of the nature of the important changes which take place in the *tenacity* of wrought iron, when subjected to various kinds of treatment, more particularly as regards the employment of wrought iron in the case of railway axles, &c. At all times, any addition to our knowledge of the nature of those causes which induce changes in the tenacity of wrought iron, ought to be considered as a subject of much importance, seeing that in so many cases our lives depend on the tenacity or strength of a piece of that material. This subject has, however, of late become infinitely more important, on account of the truly wonderful success and extension of the railway system, and as the whole of that vast improvement, in consequence, rests its success on the strength and tenacity of wrought iron, any addition to our knowledge on that subject cannot, I trust, but be considered of value.

The subject has, however, received much additional interest, on account of many *theories* and much controversy, which has arisen in consequence of an opinion which has been given forth from rather a prominent quarter, viz. the French commission appointed to investigate the *causes* which led to the late disastrous accident on the Versailles railroad. The most remarkable part of the conclusions which that body gave forth, was in substance this:—namely, that however tough and strong a railway axle might originally be as it came from the hands of the maker of the said axle, that the very fact of its being caused to revolve day after day in connexion with the rails, would ere long, through the agency of some mysterious electrical! or *magnetical* influence, have its nature, as regards the toughness or *tenacity* of the iron, so impaired, as to become at length totally unsafe and unfit for use.

A more truly alarming and uncomfortable doctrine could not have been produced than this, inasmuch as we should never be able to know when the point of unfitness was attained, except through the occurrence of one of those disastrous and melancholy accidents which have but too certainly attended the breaking of a railway axle; and as the above opinion was based on conjecture as to the supposed influence of the most dark, hidden, and mysterious of all nature's agents, we might therefore have groped about in vain for such a knowledge of the subject as would be most likely to prevent such dangerous changes taking place in the tenacity of the iron; and moreover, by having our attention diverted to so *non-understandable* a class of natural causes, we should be likely to cease to search for the cause, cure, and prevention (which I trust my experiments will go to prove, have more intimate connexion with our workshops and workmen, than with philosophers and their laboratories); and as the results of the experiments I have made on this subject are applicable to the treatment of wrought iron generally in reference to its every day use, I trust that the results may be found of practical value, the more so as they go to prove that we have the cure and prevention entirely at our command, without calling for the slightest additional labour or expense in the treatment of wrought iron.

From former *practical* experience in the working of iron in the process of forging, I had always observed that, however tough, tenacious, and excellent in quality a piece of wrought iron might originally be, that, by certain treatment, that tenacity might be all but entirely destroyed; and as such treatment is very frequently absolutely necessary in the forging of wrought iron into certain forms, the knowledge of how to remove the bad effects consequent on such, became important to know. I am happy to state that this knowledge is so simple and easily put in practice, that I trust, in future, no piece of forged wrought iron will henceforth be applied to its purpose without having been passed through so simple and salutary a process, which you will find requires neither skill, labour, or cost worth naming. Having made these observations, I shall now proceed to work.

It either is or ought to be known to all practical men concerned in
Vol. V.—No. 60.—SEPTEMBER, 1842.

the working of wrought iron, that if a piece of the very best and toughest iron is hammered in the process of forging until it ceases to be red hot, that the effect of such *cold* hammering, as I may term it, is to cause the iron to become so brittle, that it will in many cases break across in the process; or if it does not at that time, this process of cold hammering has so removed and destroyed its tenacity, as to render it capable of being broken with the slightest blow; in order to prove this by direct experiment, I took a bar of the very best wrought iron, $1\frac{1}{2}$ inch square, and subjected it to the following experimental tests:—

Experiment 1.

A bar of the very best $1\frac{1}{2}$ inch square wrought iron, at temperature 60° , was laid over the edge of the anvil, *Fig. 1.* the end projecting

Fig. 1.

about 2 $\frac{1}{2}$ or 3 inches over at A; with 9 heavy blows of a large sledge hammer it broke off short, as indicated in the figure, the fracture exhibiting that clear crystalline texture due to a good quality of iron at that temperature.

Experiment 2.

Part of the same bar of iron was taken and heated red hot, and hammered till it was nearly quite cold; when it had arrived at temperature 60° (same as the first experiment), it was placed on the anvil with the end overhanging as before, at A, one slight blow broke it sharp and square across, the fracture exhibiting a most beautiful *close* crystalline grain, more like the fracture of steel than iron, but such a fine grain as would (and indeed very frequently is) considered a proof of good quality, that is, fitness to be trusted to! So much for the appearance of the texture as a criterion of fitness. Here, then, we have distinct proof, by this experiment, that we have reduced the blow or shock-resisting quality of the iron fully $\frac{1}{2}$ by the effect of *cold* hammering alone; and what renders the knowledge of the effects of such a process the more important is, that in most cases we shall find that, in order to give the piece of forged work the requisite finish and fine surface, as they come from the hands of our workmen in that department, that this very cold hammering and *smaging*, as it is termed, is required, the more so as it is by such a process that iron forgings are so finished *from the hammer*, so as to require the least possible labour after, and as every good workman in that department is anxious to turn his work out of hand with the very best surface on it, which this cold hammering enables him to do, it is not a very easy matter, and (as I will soon show) *not at all desirable*, to require them to discontinue the practice, which many have endeavoured to do from want of a full knowledge of the subject. *There is nothing inherently wrong in this practice of cold hammering*—far otherwise; the evil rests with the applying such a cold hammered piece of forge work to its purpose without having been passed through the *curing process*, which is simply this, namely, to heat the piece of forged work in question to a *dull red heat*, and lay it down to cool at its leisure. The value of this most simple process will be well illustrated by Experiment 3.

Experiment 3.

A piece of the same bar iron as employed in the preceding experiments was, after being heated red hot and hammered till cold (which

cold hammering produced, as is usual, a most beautifully smooth surface, in which good workmen delight), again heated to a dull red heat, and laid down to cool at its leisure; being then at temperature 60° , it was placed over the edge of the anvil as before, and after receiving

105 of the most vigorous blows of the same sledge hammer as was employed in the preceding experiments, it exhibited the most extraordinary evidence of tenacity, by resisting all attempts to break it, having passed into the form as given in Fig. 2, that is, bent quite double, and the excessive distention across the part B—C causing the width across at E to decrease at least $\frac{1}{2}$ of an inch, while the compression at the centre of bending caused the metal to expand a like quantity at F G. Every practical man knows that this is a most severe test of the tenacity of iron, and which the piece in question stood with the most perfect success, for even after having received 105 blows, no evidence of fracture was visible.

This third experiment then brings us to this most important conclusion, that there is no inherent evil or ill effect produced by cold hammering, *but far otherwise*, namely, that by subjecting wrought iron to the most violent hammering or compression at a low temperature, and then submitting the iron work so treated to the simple process of heating red hot and slow cooling, that we have enhanced its tenacity or shock-sustaining qualities at least twenty times. Here, then, we get hold of some *facts* which I trust I may consider to bear with some important effects on the treatment and use of iron, especially in the case of its application to railway axles, as from their very required form, the process of cold hammering and swaging is all but absolutely necessary in forging the bar of iron out of which they are formed into the requisite shape.

Fig. 3.

The above Fig. 3 is the form of a railway axle (one half the length only is shown) as they are generally made, the bearings being at A, the wheels being keyed on the part B. In forging such an axle, the bearings are formed with the requisite collars at the ends by hammering the iron at that part by a series of direct blows of the hammer, and giving them the requisite finish or precision of form, so far as can be done previous to being finished on the turning lathe, by means of tools called swages, which consist of two pieces of iron covered with steel, and made smooth; and being of very nearly the same curve as the bearing of the axle, they enable the smith to transmit his blows with much greater precision, and also avoid all hammer marks.

Fig. 4 may perhaps serve to convey some idea of what is termed a swage. A and B are the upper and under swages, which enable the smith to transmit the blows from the sledge hammer with the greatest precision, and to convert the blow of the hammer into a *compressing* effect over a very considerable surface of the cylindrical bearing of the axle. During the process the axle C would be laid in the semi-circular hollow of the under swage B, while the upper swage would be kept firmly pressed upon the axle bearing, so as to cause it to receive the blow the instant it was given on the top of the upper swage A. I have been the more anxious to detail this process, as it is to the effects of this swaging that we are to ascribe the majority of cases of broken axles. Not that the process is bad in itself—far

Fig. 4.

otherwise; it is only bad in its effects, provided we stop there. But if we only take the trouble to anneal such a swaged axle *after* it has received the most severe compression, by swaging or hammering at low temperature (*i. e.* 60° , or thereabouts,) by simply heating it to a dull red heat, and laying it down to cool at leisure, we should then, as in the case of experiment 3rd., have a most extraordinary degree of toughness and shock-resisting quality conferred on it, in place of such a state as detailed in experiment 2nd., with, in all probability, such disastrous results as there are but too truly sad records of.

I have also been anxious to detail these experiments, as they appear to me to bear directly upon the subject of railway accidents which have arisen from broken axles, in the investigation of which the *appearance* of the fracture of the broken axle has been made the criterion of fitness or otherwise of the iron for such use, and in many cases the iron has been condemned in consequence, when the real truth might in all probability be that it was simply the result of cold hammering, without the subsequent process of annealing at a dull red heat, as before named.

In the case of experiment 2nd we have what would in general be considered evidence (so far as texture or grain of the fracture goes) of very fine quality of iron; but what was its actual fitness I leave my readers to judge by the result of that experiment.

With all due reverence for *scientific* research, I cannot but think that in this subject, as in many others of the same nature, there is too great a tendency to hunt after explanations of causes and modes of prevention which, as before said, we find a much shorter and satisfactory road to, by searching for them in our workshops rather than in our laboratories. I trust my readers will in general agree with me, that the result of these simple experiments tends to illustrate what I state on this head. Our workshops are (if rightly looked into) the true schools of practical science, wherein theory may be seen in its *really* true state, namely, accompanied with *all* the circumstances which conspire to give the true result.

Experiment 4.

Being desirous to try the effect of temperature in influencing the appearance of fracture as regards crystalline texture, a part of the same bar, as in all the preceding experiments, was taken and warmed from 60° to 100° . Such was the effect of this 40° of additional heat,

Fig. 7.

that after receiving about 50 blows over the edge of the anvil, it passed into the form given in fig. 7, the fracture being entirely fibrous, like wood, of a fine lead gray colour, and totally free from the appearance of any sparkling crystals. This experiment, then, warrants the conclusion, that the appearance of the fracture is also no criterion of the quality of the iron, if temperature be left out of the question, inasmuch as 40° has not only vastly improved the tenacity, but also wrought an entire change on the aspect of the grain of the iron. It is well known to practical men that a very few degrees of heat will most materially

affect not only the appearance of the fracture of iron, but also its tenacity.

But for my reluctance to occupy more of the space of your excellent journal, I should most gladly have given farther details and experiments; but I trust such as I have endeavoured to describe will be in some degree acceptable, and be productive of useful results. I would most strongly recommend all who are interested in such matters, and who have the opportunity, to repeat the experiments themselves,† as I doubt not the results would not only agree with what I have found and stated, but also tend to rivet the recollection of them in their minds, as the subject is one of the very highest importance to all, especially to those whose professional character and success may be influenced by possession or otherwise of such plain workshop facts.

I have no desire to make any great claim of discovery here, but I shall feel highly gratified, if what I have brought to light as to the vast accession of shock-resisting quality conferred on wrought iron by the combined action of cold hammering and subsequent annealing should prove, as I am confident it will, a substantial benefit to all who have either their lives or property depending on pieces of wrought iron, whether in the case of a railway axle, or other application.

I am no advocate for over-burdening the attention of engineers with compulsory clauses in specifications, but I would most strongly recommend attention to annealing of all bolts and axles, on which much depends. The recommended process requires no extra expense or trouble worth naming, and companies would do well to see that such was attended to.

Bridgewater Foundry,
near Manchester,
Aug. 1, 1842.

Yours most respectfully,
JAMES NASMYTH.

NOTES ON STEAM NAVIGATION.

Engine Frames.—The foot or projection descending from the diagonal stay to the condenser or main centre bracket is, in our opinion, superfluous and inexpedient. If the attachments of the main centre to the bottom are such as they ought to be, this projection from the diagonal stay can have no upward pressure thrown upon it; and if the bottom attachments are insufficient, the diagonal stay is unable to resist the upward pressure without injurious straining and vibration. The attachment for the main centre is best, we consider, when cast in the form of a bracket on the sole plate, as in the engines of the *Trent* and *Isis*, by Messrs. Miller and Ravenhill. The bottom part of the engines of Messrs. Maudslays and Co. consists of too many pieces: the sole plate is one casting, the condenser another, and the main centre bracket a third; and these parts have to be fixed together by bolts, and there is a joint of great superficies between the sole

* We sincerely hope that Mr. Nasmyth will not hesitate to favour us with all the information he can upon so important a subject, and we feel assured that we are only echoing the sentiments of our readers in expressing such a desire.—EDITOR.

† And record them in the *Journal*.—EDITOR.

plate and condenser, which is undeniably a very bad thing. In Messrs. Miller's engines all these parts are cast together: the sole plate, condenser, and main centre brackets consist of only one piece which is certainly much the best system.

All the bolts in the framing for the purpose of connecting the several parts of it together should be turned with a little taper, and the holes should all be widened out. If this be not done, the framing will be very likely to work. Where there is much side strain upon the bolts they should be of steel. The soles of the plummer blocks and the places they rest on upon the frame should be planed all over; the outsides of the paddle shaft brasses, and the insides of the plummer blocks should also be planed all over; fitting strips will work into the substance of the brass, and the bearings will get slack sideways without the possibility of tightening them. Horns to the crank beams are unnecessary, if the framing be well fitted and bolted, but if adopted, should have some means of being tightened sideways as well as fore and aft, in the sockets on the beams in which the horns slide. A horizontal cross between the engines is a very useful attachment; and the connecting pieces at the end of the engines between the frames should extend upwards and downwards on the columns, so as to obtain as firm a hold of them as possible. The surfaces should all be planed, and the holes widened. A common planing machine may be made to plane sole plates, cylinder faces, or framing by fixing a bracket to carry the tool upon the carriage, and bringing the thing to be planed to the side of the machine, and there fixing it. A string attached to a ratchet operating on a screw may be easily made to move down or forward the cutter.

Valve and parallel motions.—The valve motion of one engine is identical with the piston motion of the other engine; and the parallel motion shaft of the one engine, by being extended to the other engine, might be used to work that engine's valve. A combination, too, of the motions of the two engines might be used to work the expansion valve, so that both the slide valves and expansion valves might be worked without either cams or eccentrics. To carry this out in practice it would be necessary to have a solid shaft within a hollow shaft, extending from engine to engine, the parallel motion of the one engine being connected with the solid shaft and the parallel motion of the other with the hollow shaft. The parallel motion, then, of the starboard engine would work the larboard valve, and *vice versa*. The expansion valve might be a slide valve working on the inner flat surface of an ordinary short D, with the upper tails connected so as to form a port, and wrought by a spindle through a hollow valve rod. The motion proper to the expansion valve might be obtained from the combined or antagonistic motions of the solid and hollow shafts, which sometimes move in different directions, and at other times in the same.

The best sort of foot and discharge valves would be the slide valve, and indeed the valves of the several pumps might also be made slide valves, with much advantage. The slide valve will neither make a noise, nor get gagged with chips or dirt. By way of parenthesis, we may remark that the slide valve seems to be peculiarly well adapted for the feed-pumps of locomotives. If the air pump were furnished with a slide instead of flap valves, it might be made double-acting, and with half the size would maintain a better vacuum in the condenser than is attainable by the existing modes. There would then, of course, be no valves in the bucket, which would become, in fact, a common piston. It would be easy to work the injection slide by the engine, so as to apportion the quantity of water to the quantity of steam—a measure of each being admitted every stroke—and to make the rate of its admission more nearly identical with that of the flow of steam into the condenser. This would probably have the effect of making the vacuum steadier, and would prevent the engines from being choked with water when brought up in a sea way, if used in conjunction with a cataract.

The most convenient way of packing slide valves is from the back. The packing screws should come through a cross bar supported by proper lugs in the casing, so as to take the strain off the door, and should then extend through brass bushes rivetted into the door, and

be provided with a jam nut outside, to prevent any dripping of water, or escape of steam. It is common with some engineers to let the packing project beyond the face of the valve an inch or two, little pieces being cast on the cylinder to continue the circle of the valve, and afford a support for the packing beyond the face. Messrs. Maudslays make the packing merely to abut against the face, without going beyond it. This method requires the length of the packing to be determined with great exactness previous to its introduction; and if it swivels the least on the back of the valve, there will be a vacant space at the one corner, and a double thickness of packing at the other.

The packing port should always, if possible, be opposite to the port of the cylinder, and when it is not opposite it is very important that the valve, if short D, should have the upper and under portions connected by three rods; indeed, in all large engines three rods are best. When there are only two, the valve at the extremity of its stroke is apt to bend back from the face, and will generally wear taper. The valve rod is often, in the case of short D valves, attached not immediately to the diaphragm of the valve, but to a malleable iron jaw, which is secured to the valve diaphragm. But we think it the simplest way for the valve rod to go at once through the valve diaphragm, with nuts upon the under side, and for the square pin by which the valve is moved to be supported by two brackets cast on the valve diaphragm, there being a little play left fore and aft in the square eye of the valve rod, to admit of the valve being pressed forward as the faces wear, without interfering with the stuffing box above.

Paddle centres.—We do not think favourably of the plan of boring out the eyes of the paddle centres, turning the bosses on the shafts, and fitting the centres on with a single key. When once the centres get rusted in their seats, when fitted in this way, it is next to impossible to start them, and if the vessel has to go into dock, it will sometimes be necessary to break the centres before the paddle rings can be drawn towards the sides of the ship. Nor do we think well of the plan of putting the centres on in two halves. It is almost impossible to prevent such centres from becoming slack upon the shaft, unless they be encircled by a malleable iron hoop. We like best to see the bosses on the shaft, and the eyes of the centres square; each centre made in a single piece, and fixed on the shaft by means of eight good thick and wide keys. A cut should be made with a chisel at the head of each key, so as to raise a projection on the shaft against the end of the key, to prevent it from working out. These burs can be easily cut off at any time the centres require to be shifted, and the keys, if made of proper strength and taper, may always be started without any very great difficulty. The heads of the paddle arms should be secured in sockets in the paddle centre, with keys. We do not at all like the plan of fixing the arms with bolts to the sides of a centre indented to receive them; we have never known any of this kind of centres to be in use for any considerable time without the arms becoming loose.

Crank pins should always be made much larger than is required for strength, else they will be very apt to heat. The crank pin of Messrs. Miller and Co.'s West India packets is $1\frac{1}{2}$; of that of Messrs. Scott and Sinclair's about $7\frac{1}{2}$. We like the crank pin to be put in from the inner side, that is, through the eye of the paddle crank, and secured by a strong screw tapped into the pin pressing upon a washer of adequate strength, which rests on the crank pin eye. We do not approve of large cutter holes through the eye and pin, by which they are much weakened; and think a single steel pin of moderate diameter, driven through the crank pin and eye, sufficient to keep the pin firm, assisted with the screw at the outer extremity.

Drag links are a useless incumbrance: the end of the pin in the loose eye of the crank should, of course, be rounded, to admit the fall of the outer end of the shaft without snapping the pin, and should be steeled, so that it may not wear very fast. There should be a removable steel or brass block in the loose eye for the pin to press against, rounded to the shape of the pin, and slipping into its place in a dovetail. This should be on the driving side: on the backing

side there should be a small square block fitted into a recess in the crank eye, and pressed against the pin by a screw with a jam nut, so that there may be no back lash in the loose eye, when the sea strikes the paddle-wheel. The screw should always be on the backing side, else the continual pressure on the point of the bolt will be apt to rivet it in.

Different modes of Propulsion.—Up to the present time the paddle-wheel is undoubtedly the best; but we have high expectations from a very novel plan of propulsion devised, and now in the process of being matured, by the Messrs. Whitelaw, of Glasgow. Mr. Whitelaw's screw has succeeded far better than most engineers ever expected, but it is certainly as yet less efficient than the paddle-wheel. The Great Western *cognoscenti* have adopted the screw, and their iron leviathan, and intend to drive it with a belt. A belt driven by horses' power and a belt! Who, after this, can refuse to put his foot on Indian rubber? We know not if this be an emanation of Mr. Babbage's genius, or a device of the chivalrous Mr. Guppy; and we think it to be regretted that the public is not more specifically informed of whom the brilliant thought is principally due. Our grand old country certainly had but little idea of spinning-wheels on so magnificent a scale, else they might have bequeathed some hints of very great import. They might perhaps have told us that belts are apt to stretch and slip, when there is much strain put upon them, and that salt and heat and steam do not act beneficially upon leather. But such legacies have been left us, and the days of spinning-wheels are gone, we must now make up our minds to wait with resignation for the issue of the Great Western experiment, though we question whether it will be brought to an issue for ten or twenty years to come. We really think it would have been well for the Great Western people, had they gone to Messrs. Maudslays and Field for a paddle-wheel for the Great Western. Had they done so, they would have been sure of an excellent vessel, she would have been afloat long ago, and would have been earning money.

PROFESSOR MOSELEY'S CONTINUOUS INDICATOR.

WE think upon the whole very favourably of this contrivance, but it appears needlessly complicated and expensive, and perhaps somewhat liable to get out of order. The friction cones, we consider, are not sufficiently safe and certain in their action. A little oil falling upon them, and a little undue friction in the machine—accidents likely enough to occur, especially in a steam vessel—would cause the cones to turn round, without carrying the wheel-work with them, and thereby vitiate the indications. These evils in our estimation are susceptible of a remedy, and we should propose a form of indicator somewhat after the fashion of that figured in the subjoined rude sketch, as less objectionable, perhaps, than Professor Moseley's, though without any pretensions to the character of a matured or unobjectionable scheme.

A A are the springs; B the links connecting the C is the cylinder of the indicator; D the cock for inserting it in the cylinder cover; E a ratchet wheel, circled by a ring, with a number of internal palls, as in patent windlass, and terminating in a lever, F, with a long slot, in which the rod, G, may be, by bell-crank, H, moved either towards F, or towards E. I is connected with the engine and if the pin moving in the slot of the lever, F, is

always stationary, it would always carry round the ratchet an equal distance. But when the pressure in the cylinder is increased, piston of the indicator is forced farther up, and the rod, G, is driven

nearer to the centre of E, and consequently carries the ratchet round a greater distance. The slot should of course be made so that G might be carried to the very centre of E, though not so shown in the figure. Instead of a rod, G, a string with a weight or spring for bringing it back might be employed: and instead of the bell-crank, H, a chain or piece of silk or catgut, with a couple of pulleys and a spring, might be used. These pulleys, or one of them, might manifestly be made spiral, so as to move the pin of G out and in, according to any desired ratio; or the same effect is accomplishable by a suitable construction of the spring.

We do not think it of the least use to register the pressure of steam beneath the piston as well as above, in any double-acting engine; as, if the valves are properly proportioned, the upper and under pressures must be always the same. It is desirable to ascertain by a common indicator that the action in the up and down stroke is identical; and then the registration of the difference of pressure during one part of the stroke will be a correct indication of the engine's performance.

We are glad to find that Professor Moseley's indicator is about to be applied to the Great Western, and we anticipate vast benefit to steam navigation from its application to steam vessels in general. We trust Professor Moseley will urge the advantages of such a species of registration upon the attention of steam ship owners. It is of the last importance, and the public is greatly indebted to Professor Moseley for his successful labours in removing many of the difficulties which stood in the way of the establishment of a comprehensive and efficient system. We shall be greatly disappointed if he fails to follow these labours up, or neglects the steps necessary to render them beneficially available in practice. Some representation should be made to the Steam Association on the subject.

THE ELEMENTS OF STEAM IMPROVEMENT.

One of the most important improvements in the steam engine developed of late years is expansion; and although it can scarcely now be called an innovation, yet it has not, up to the present time, come into universal use, and where adopted, has not been carried to that degree to which it might be beneficially extended. In Cornwall, it is true, expansion has accomplished the greatest wonders, and in our largest steam vessels the most eminent benefit has been derived from its use; but in many steam vessels, expansion is very little or not at all practised, and in those in which it has been carried farthest, it has not, we think, been carried sufficiently far. We know it will be objected to, that to carry expansion much farther in steam vessels would require high pressure boilers, and that such boilers are too dangerous to be admissible. But we do not think high pressure boilers, if made as they ought to be made, in the least more dangerous than the low pressure boilers in ordinary use. On railways they are regarded without apprehension; and among the innumerable locomotive boilers in use, there has been scarcely any example of accident. There would, therefore, seem to be no good objection to locomotive boilers in steam vessels on the score of danger, and they have already been introduced by Messrs. Bury and others in river steamers with eminent success. But there is a serious objection to them in the case of sea going steamers, in consequence of the deposition of scale, which would soon prove destructive to the brass or copper tubes. This difficulty, however, is surmountable by the use of some of the contrivances already before the public for keeping the boilers supplied with fresh water; and the necessity of those contrivances to locomotive boilers, confers upon them an importance to which they would not otherwise be entitled.

There are two modes of returning the same water continuously to the boiler, so as to obviate the necessity of replenishing the boiler with water from the sea—the one is to condense the steam by the interposition of cold surfaces, the other to cool the water which has become heated by the condensation of the steam, and use it over again for the purpose of condensation. The first plan is that carried out in Hall's condensers, and in the condensers of Mr. David Napier and others; the second is known as Symington's system of refrigeration: and we think it important to inquire which of these plans is the least

objectionable, and whether one of them, at least, may not be carried out in practice without giving rise to evils that will more than neutralize the benefits derivable from an extension of the principle of expansion.

The condensers of Hall require to be provided with large pumps worked by the engine; they occupy considerable room in the ship, and the weight of water and weight of metal in them are both very great. The refrigeratory pipes require to be made strong enough to resist the atmospheric pressure, and all the joints, of which there are a vast number, require to be particularly good for the same reason. These are serious objections, and another, also of considerable weight, is to be found in their expense. Condensers for engines of 300 h. p. cost several thousands of pounds, and contain about *ten miles* of pipe.

Mr. David Napier's condenser is only applicable in the case of iron vessels, and has the same disadvantage as Hall's in having the pressure of the atmosphere to sustain. It is, however, less expensive, but is rather susceptible, we apprehend, of derangement from leakage, and it is almost impossible to repair it when deranged. Symington's plan consists in leading a flattened copper pipe proceeding from the hotwell forward and aft on the outside of the ship near the bilge, so as to be always beneath the water, and out of the reach of injury either from ice, barges, or buoys, as well as from the ship taking the ground. This pipe is so made as to possess the requisite surface for cooling down the water proceeding from the hotwell to the temperature adequate for injection; and is at the same time so nicely fitted to the vessel as not to constitute any appreciable impediment to her progress. Indeed, we do not see why this pipe might not be so constructed as to form *pro tanto* the copper of the vessel, which, in effect, it would be if made with only a very small projection and a considerable depth. In Symington's plan this pipe forms the whole apparatus—there are no pumps or other machinery to work, and as the condensation is not performed within the pipe, it has no atmospheric pressure to sustain, and therefore may be made of light materials, and without any particular care in jointing. Indeed, even if there were a hole purposely made in the pipe, it is very questionable whether a drop of water would leak either in or out, the pressure within and without being just about the same.

It would be foreign to our present purpose to enter into any enumeration of the various benefits to be derived from feeding marine boilers with fresh water. It is sufficient to say that they are eminent and manifold, and involve, to a considerable extent, the question of economy of fuel. In muddy rivers, too, it is very important, after starting with clean water in the boilers, to use the same water over and over again, and we believe that, in such situations, this will be found the only remedy for priming. But these considerations, though important, are poor and insignificant compared with those which flow from an effectual extension of the principle of expansion in steam vessels, and to which the use of fresh water in the boilers is, in our opinion, indispensable.

We understand that Symington's plan of refrigeration has been applied to several steam vessels with eminent success; but one vessel to which it was applied, the *City of Londonderry*, it was subsequently removed from. This certainly looks unfavourable; yet, if the plan has been found to answer well in the case of some vessels, it is difficult to perceive why it should fail to answer universally. The most natural supposition therefore is, that the failure in the case of the *City of Londonderry* was the result of accidental circumstances, such as will often befall the best devised schemes, but which are always susceptible of rectification. As we happen to be intimately acquainted with the causes which led to the removal of Symington's apparatus in this particular instance, we shall briefly state them, partly as an act of justice to that scheme, and partly to exemplify how easily the most trivial and irrelevant circumstances may sometimes conspire to condemn and render vain even the best contrived arrangements.

Anteriorly to the application of Symington's plan, the *City of Londonderry* was an old and had always been a slow vessel: it was resolved upon to lengthen her, with the view of increasing her speed, and the occasion of this alteration was seized upon for the application of

Symington's contrivance. When the vessel was tried after having been lengthened, she was not found to be as fast as was anticipated, and the fault was thrown upon Symington's pipes for obstructing the passage of the ship through the water. These pipes were therefore taken off, but the vessel did not go any faster in consequence, and the pipes would perhaps have been applied again, had not the event of the vessel being nearly as slow as ever so discouraged the owners, that they deemed it inexpedient to go to any farther expense. Even had Symington's plan been re-applied, she would have still been inefficient for their purposes; she was therefore laid aside, and is now broken up.

It is a natural objection to Symington's plan, that the pipes on the outside of the ship are peculiarly liable to injury. In this belief we ourselves participated, but experience has proved the objection to be unfounded. The *City of Londonderry* encountered several severe storms in the Bay of Biscay, without the pipes sustaining the slightest damage; and in the other cases in which they have been applied—as in the *Dispatch*, where the plan has now been in operation for some years—no injury to the pipes has ever been found to occur. Indeed, after having given much inquiry and consideration to the subject, it is our decided belief that Symington's plan is not only the best for keeping boilers supplied with fresh water at sea, but that it is unattended with any evils or inconveniences unknown to the common method of condensation. The expense, too, is not great; the direct advantage is not inconsiderable; and the indirect advantage of such magnitude as to have induced us to give this mode of condensation so conspicuous a place in this dissertation.

Expansion is the most effectual known agency for economizing fuel; high pressure steam is indispensable for efficient expansion; and locomotive boilers are necessary to the use of high pressure steam in steam vessels with safety. The use of locomotive boilers involves the necessity of feeding the boilers with fresh water, and this is best to be accomplished by Symington's plan of condensation. It is also expedient that the locomotive boilers used in steam vessels should be provided with some species of self-acting feed, as the quantity of water in such boilers being small, the water level, without some such expedient, will be liable to great and sudden fluctuation. But upon this topic we are now unable to enlarge, and must reserve its consideration for our next number.

CANDIDUS'S NOTE-BOOK. FASCICULUS XL.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

L. GEORGE ROBINS most assuredly did not consult Welby Pugin, when, in his late advertisement of the sale of Weddington Castle, he spoke of Lugar as "an artist possessing a perfect knowledge of Gothic architecture." No doubt he would say just the same of any one else who had built a castellated pigstye, which was to be knocked down by his hammer. George is privileged to puff—no matter how impudently—for it is his vocation. But it is lamentable to see the same sort of nauseous puffery indulged in where there ought to be something like reasonable opinion assigned for the praise that is bestowed. It is a pity that, instead of an Income-tax, a tax was not levied on superfluous and nonsensical epithets. "Splendid" and "Elegant" have been so bandied about of late as to have lost all their value, and almost their meaning, too. In some cases—and those not a few—they might be supposed to have changed their meaning altogether, and to have become synonymous with "paltry" and "trumpety." With advertisement and paragraph writers everything is, in fact a *trump* card: they have nothing but trumps dealt to them, and they themselves deal in nothing but trumpeting. Even the *Times* has lately got hold of a penny-trumpet—that, perhaps, of some penny-a-liner—with which it has been squeaking out the praises of

one or two publications, which formerly, supposing them to have then appeared, it would not have condescended to notice at all.

II. Mr. Moxhay seems to resemble Lord Byron, inasmuch as, on waking a few weeks ago, in the morning, he found himself suddenly become famous. Within the last month, his name has appeared and his building has been spoken of in almost every newspaper, and that in a manner more flattering to both, than to some of the "Dons" in the profession and their handyworks. Not a few have been the peregrinations made to Threadneedle Street, by artists and people of taste, for the express purpose of viewing a piece of architecture whose character is so remarkable, on account of the exceedingly important share which sculpture has in it. The artist employed upon the last has performed his task with more than ordinary ability, and has produced what will bear deliberate examination as a work of art—as something more than so much ornament, intended merely to aid the general effect. Whether what has been here done by a private individual will have the effect—either general or partial—of introducing sculpture into architecture, as a more important feature in it than it has hitherto been made in this country, it would be as hazardous to prophecy as it was to predict the London earthquake.

III. It is justly remarked by the writer of the "Spirit of Architecture," that the engineer—and, he might have added, the builder—is now treading upon the heel of the architect. Well, let us then hope that those who bear the latter title will feel spurred on thereby, and endeavour to rouse themselves from their lethargy—from the drowsy system of giving us literal copies of a few of the forms or parts belonging to the style professedly adopted. At the best they show themselves no more than mere copyists, unable to think for themselves, or to get on at all without incessant prompting: nor is it unfrequently they betray how utterly ignorant they are of the real character of the style they profess to follow. In fact, as far as they study style at all, very many seem to have no other notion of doing so than merely by piecemeal, and in fragments. They can pore over its separate bits—they have its alphabet tolerably well by heart; but farther than that they are either quite unable to get, or too indolent to strive to advance. They take no *grasp* of any style; they do not attempt to make themselves masters of it. Perhaps, after all, no wonder such should be the case; for if the study requisite for attaining a complete knowledge of style, composition and effect, be not felt to be a delightful pursuit, it must be felt to be a confounded bore. The *bored* or *moored-boards* will content themselves—what a virtue is content!—with what they can pick up out of "Stuart," and other works of that kind. But they would also do well to reflect—if only because it may touch their own pockets—that they are not exactly the patentees of the works they make use of so very liberally, and study very scantily. The engineer and the builder can take a leaf out of them, just as well as themselves, and thereby become every inch as classical. Little occasion is there for an architect for such things as the York and the Nelson column, when an engineer would do quite as well, perhaps even better. Little occasion, too, is there to employ a sculptor, when anything rough-shaped into the form of a man will serve for the statue that is to be hoisted up to such a height as to render seeing it out of the question.

IV. It is somewhat singular, that while polychromy has been adopted at Munich for one or two buildings, the Ionic monopteral temple in the "English Garden," the Post Office, and Great Theatre, the throne-room of the palace should be entirely white and gold; although a very good opportunity was there offered for trying the full effect of polychromic architectural decoration precisely after the antique fashion, by decorated colouring and painted enrichments applied to the mouldings and surfaces of the various architectural members. Probably the monochrome or achromatic style of embellishment adopted for this apartment was intended to contrast with the rest, all of which are painted with subjects in fresco; which last circumstance, and that of the rooms being throughout of nearly the same size and shape, occasion a degree of monotony that it would have been better to avoid. No "Episodes of Plan" are to be found in the Neue Residenz at Munich, though the throne-room itself admitted of being rendered a rather striking one, since its purpose admitted of

a form being adopted for it that can very seldom be introduced at all. So far from being inconvenient, a semicircle, with the throne placed on the chord or straight of the room, either between columns, or within a tribune forming a smaller semicircle, would have been better adapted to the particular purpose than any other shape. It would then, too, have been manifest at once that the room was especially intended to be and to remain what it actually was, and that it had been planned expressly for the use to which it was applied, and for no other.

V. Wolff's remarks on the Berlin Museum are one of the ablest and most interesting pieces of architectural criticism I have met with for some time—searching, and perhaps a trifle too hypercritical, but the building itself is one that will bear a little more probing than usual. As to *probing*, it is not every critic who can perform the operation dexterously; neither is it every architect who relishes the idea of its being performed upon himself. Well, therefore, would it be, were architects to anticipate critics, and thoroughly probe their own designs in the first instance, with an unflinching hand; at least, well consider what objections are likely to be made by others, and whether they can be at all parried.

V1. There is a note to an article upon Greece in the last No. of the Quarterly Review, which stimulates curiosity not a little; for it mentions a "magnificent" work by Demidov on the Remains of Grecian Architecture, but without specifying anything farther than that the text is in Russian, unaccompanied by either a French or English translation of it. Whether it is worth translating in itself, is more than the writer in the Quarterly can tell, for he confesses his inability to judge of more than the plates; yet he might as well have mentioned the date, and something that would have served as a clue to others, in making inquiries relative to a work not likely to be met with by mere accident. It does not follow that because the reviewer himself could give no account of it, no one else can; and at any rate he might have extended his note, and said something of the engravings, since it is to them, it may be presumed, that the work is mainly indebted for its "magnificence." As it is now some time since the Quarterly Review has favoured us with any architectural paper, it would do well to found one upon M. Demidov's work; for if there is anything fresh in the plates, there is in all probability some original matter in the text—perhaps some original remark also, and if so, it is quite as deserving of being communicated to the readers of the Quarterly as Fanny Burney's "small-beer chronicles" about herself and the "sweet Queen." It is to be hoped that Queen Victoria has no such chroniclers and diary-keepers about her person. The court newsman gives us quite enough of "small-beer" doings at the palace.

ON THE STRENGTH OF TRUSSED GIRDERS.

(From the American Journal of the Franklin Institute.)

Details of some Experiments upon the Comparative Strength of Trussed and plain girders of wood, made at the Philadelphia Exchange, during the construction of that building in 1832. By JOHN MCCLURE and ELLWOOD MORRIS, C.E. Reported by the latter.

THE experiments which have been made upon the relative strength of girders, trussed and untrussed, are so few—that the following details may be found interesting to persons engaged in construction; particularly as the mode of trussing by suspension, therein tested, is becoming more and more extensively used in this country, and is really susceptible of being made very serviceable in many situations.

These experiments were undertaken with the view of ascertaining the proximate value of wrought iron suspension trusses for girders, which were about that time brought forward conspicuously here, as a new and useful improvement in carpentry; though at least in one instance they had been used many years before in this country; viz., by Lewis Wernwag, the celebrated carpenter,* who applied suspension

bars, one and quarter inches square, to stiffen the main longitudinal floor beams of the bridge over the Neshaminy creek, in this state, which was built by him in the year 1808. (See the annexed sketch which represents a side view of the suspension truss used in the bridge referred to.)

We have taken the pains to ascertain from Mr. Wernwag himself the date of the construction of the Neshaminy bridge, as it carries the application of the suspension girder truss somewhat further back into past time, than has heretofore been expected; though the writer has lately been informed by a gentleman distinguished for his antiquarian researches, that such trusses were in use upon the continent of Europe even antecedent to that time.

The now recorded history of the wrought iron suspension truss for girders, as far as known to the writer, is as follows:—"In 1821, Mr. R. Stevenson, of Edinburgh, designed a bridge for the river Almond, in which the principle of supporting a roadway by iron bars passing underneath, was first adopted."* In 1822 the same principle was recommended by Mr. H. Palmer, to be applied in carrying his railway, of a single line, over streams or vallies.† In 1824 Mr. A. Ainger submitted a suspension trussed girder to the Society for the encouragement of Arts; to which we shall presently more particularly refer, and which was successively applied to practice. In 1828 girders trussed by suspending rods were used with manifest advantage in several buildings, by Mr. Joseph Conder, who claimed the merit of their invention, as did also Mr. A. H. Renton, Civil Engineer.‡ All these gentlemen, however, without their knowledge, had been anticipated in this matter by Wernwag, at the Neshaminy bridge, as before mentioned.

In addition to the above, the writer may state that in 1833 he examined a wrought iron suspension truss, which had been applied some years before, on a large scale, to uphold the central parts of Flat Rock bridge, (of 198 feet span,) over the Schuylkill river; which bridge—constructed with *very slender* curved ribs of three inch plank—had at that time yielded considerably, and since has fallen down. In 1834 he measured a horse bridge (built by Wernwag) upon the Chesapeake and Ohio Canal, near Harper's Ferry, of 52 feet span, which was trussed like fig. 1, the horizontal bar being 26 inches clear of the underside of the outer floor beams, which rested each upon two inverted queen posts of iron, diagonally braced against lateral motion, and rising, as it were, from the angular points *b* and *c*. This species of truss has, since that time, been applied to strengthen the girders of a number of bridges in the United States, to which it is unnecessary now to refer.§

Returning from this digression, into the recent history of suspension trussing; we will now repeat, that in the Franklin Journal for 1832, the description of a mode of trussing girders with wrought iron rods, acting upon the suspension principle, was extracted from the "Transactions of the Society for the encouragement of Arts," and accompanied by two wood engravings.

The plan alluded to was devised by Mr. Alfred Ainger, and sub-

* *Civ. Eng. and Arch. Jour.*, for Oct., 1841. "Description of the Foot Bridge over the river Whitadder, at Abbey St. Bathans, Berwickshire; by J. R. Wilson."

† Palmer's "Description of a railway on a new principle," London.

‡ Reg. of Arts, 2nd series, vol. ii, London.

§ In connection with this branch of the subject, we must not omit to add the following, from the same paper of Mr. J. R. Wilson, (*Civ. Eng. and Arch. Jour.*, Oct. 1841,) already quoted.

"In 1833 a bridge was erected on the tension bar principle over an arm of the lake of Geneva. It has 13 openings, of 55 ft. span, and is 25 ft. broad. The same plan has been adopted for two foot bridges of 138 and 81 ft. span respectively, erected several years since over the river Ness, near Inverness; and also for a bridge over the river Whitadder, in Berwickshire, at Hutton Mill, designed by Mr. Jardine, of Edinburgh, which consists of three openings of 50 ft. span. Mr. Smith, of Deanston, has erected a foot bridge of this kind, 103 ft. span, near Donne; and has also applied tension rods very successfully, for supporting the floors of Deanston cotton works, where they have been in use for many years."

* Mr. Wernwag, a German by birth, immigrated here in 1788, and is the mechanic who designed and constructed the famous timber bridge of 340 ft. span, over the Schuylkill river at Philadelphia, (recently destroyed by fire,) besides many other wooden bridges of magnitude and importance, in various parts of the United States.

mitted to the Society in 1824, who after investigating the merits of the plan—trying some experiments upon models—and witnessing its successful application in buildings—finally testified to Mr. Ainger, their sense of the merit of his contrivance for strengthening beams, by formally awarding to him the thanks of the Society. Mr. Ainger's truss, as applied to a girder of 34 ft. span, consisted of two sets of iron rods, (one on each side of a single beam of timber,) secured by screws and nuts, to abutment plates, notched upon the upper side at the ends; these rods descended so low as to admit of two supporting plates being inserted between them and the beam, and forced up against its underside by the end screws, so as to give to the girder two intermediate points of support; thus dividing the whole span into three bearing spaces of equal extent; the side view closely resembling fig. 1. This girder is described as having answered very well, it is stated to have carried a leaden flat for two years, without sensibly altering its form. Mr. Ainger also recommended that notches should be cut in the upper side of the beam extending to one-third of its depth, and filled "with thin wedges of hard wood or metal, forcibly driven in," so as to augment its strength and stiffness, by putting its upper side in a state of compression before being loaded.*

It was the article above referred to which first drew the attention of the writer to this particular subject, and induced him, in company with Mr. McClure, to undertake, in the year 1832, a few experiments upon model girders.

These models were accurately made under the direction of Mr. McClure, and were five in number; each was composed of two parts, or flitches, so united as to bear a strain together; each side, or flitch, was 53 inches long, 1.75 inches deep, and 1.16 inches broad, having together a sectional area of 4.06 superficial inches; and all the models were made of clean, straight grained, and well seasoned white pine;† numbers 1, 2, and 3, were from the same plank, and Nos. 4 and 5 from timber of the same lot and quality.

Model No. 1: Was trussed in a mode similar to that prescribed by Mr. Ainger; a single wrought iron rod exactly one-fourth of an inch square, being secured upon the upper side, at both ends, by quarter inch square pins, resting horizontally upon abutment plates one-twelfth of an inch thick, which embraced each end of the girder; this rod descended between the flitches so low as to admit the insertion of two bearing plates, *b* and *c*, fig. 1, which were forced in between it and the underside of the beams, at equal distances from the ends, and from each other, so as to give to the girder a small camber. (See plan and section, fig. 1.) And, in addition, 34 equidistant cuts were made in this model, to a depth of one-third of the whole, and tightly filled with thin pieces of hard oak well driven in.

Model No. 2: Was similar to No. 1, (fig. 1,) in all respects except that the hard oak wedges were omitted.

Model No. 3: Was a plain stick, formed by nailing the two flitches together, side by side, with four nails in the centre line, (see fig. 2, side view.)

Model No. 4: Was a girder trussed exactly like Nos. 1 and 2, except that a central bearing plate, one-sixteenth of an inch thick, was inserted between the beam and truss rod at *a*, fig. 1.

* This was conformable to the results of some experiments by M. Duhamel, who showed that when a bar of soft wood, such as willow, was cut one-third through from the upper side, and this cut filled with a thin piece of hard wood stuck in pretty tight, its ultimate transverse strength was thereby increased about 10 per cent. (Barlow's Essay on the Strength and Stress of Timber, 3rd. Edit., 1826.)

† This is the *Pinus Strobus* of Michaud's North American Sylva (vol. iii, p. 159), the loftiest tree of the American forest; it is employed here for an immense variety of purposes, and is one of the most valuable timbers which we possess. It is called *Weymouth Pine*, in Tredgold's Carpentry; and we may here remark that the concurrence of three of our experiments indicates that the ultimate strength of the white pine, used in our models—which was of the best quality supplied by the lumber market of Philadelphia—did not exceed 868 lb. for sticks of the scantling, and length of bearing, used by us. Wherefore the constant quantity *c*, of the table in Tredgold's Carpentry,

(2nd Edit., London, 1828, p. 56,) calculated by the formula $= \frac{W L}{b d^2}$ would be

509 instead of 658, as Tredgold has it, which last is certainly too high a number; for the breaking weight of our plain stick, (model No. 3,) if calculated by it, would have been 1122 lb., instead of 868 lb., (as we actually found it to be,) or thirty per cent more.

Model No. 5: Was a girder trussed in the common way—with one king bolt, two iron abutments, two hard oak braces let into each flitch nearly one-eighth of an inch—and keyed up to a slight camber. (See fig. 3, which shows the girder with one flitch removed.)

All of these models were put under strain in the same manner, their own weight being counterbalanced; viz., by resting them against two fixed supports, exactly 50 inches asunder, and applying the straining force, by a vertical pull upwards, through an iron stirrup with rounded edges, slipped over the model—which was turned bottom up—and attached to the shorter arm of an accurate steelyard, which weighed up to 1,288 lbs.; and the successive strains were put on by moving the weight of the steelyard, as in weighing, so as to add usually 56 lbs. at a time; the beam of the steelyard being adjusted to a level at each addition of strain, and the deflections being carefully measured—from a fine string joining the extremities of the models—by a diagonal scale to hundredths of inches. (See fig. 4, which gives a general idea of the experimental apparatus, *f* being a girder under trial.)

The subjoined tabular statement exhibits, at one view, the results of the trials of the strength of the several model girders; which it will be recollected, were all of precisely the same scantling and bearing length.

It must be observed that our steelyard not having sufficient power to break model No. 4, it was subsequently broken by a lever, in order to ascertain the position of the neutral axis of fracture.

The five following results were common to all the models when broken, and though similar to what have been observed by other experimentalists, they may as well be stated.

1. The neutral axis of fracture, occupied precisely the same place in all, being at four-sevenths of the whole depth down from the top, or one-fourteenth below the middle, (Barlow's experiments on fir beams fixed it at five-eighths of the depth, which is nearly the same.)

Giving, area of fibres crushed,	2.32 square inches.
Ditto torn asunder	1.74 " "

Total sectional area in superficial inches 4.06

2. The first indications of fracture, always appeared on the upper side, by the fibres crushing.

3. The signs of crushing at the time of fracture could be traced each way from the centre some five or six inches.

4. The deflections within the limit of elasticity, were (very nearly) equally increased by the addition of equal weights.

5. The place of the neutral axis of fracture, was most distinctly marked in every case, and the section of fracture, in all the models, very closely resembled that shown in Plate III of Barlow's Essay on Timber, 3rd ed: London, 1826.

The elastic strength of Model No. 1, did not exceed 392 lb.

24	1288							1.75	Rested here for want of weight, and unloaded returned to a permanent defl. of .16 in.		

A comparison of the tabular results will show:

1. That, contrary to the experiments of Duhamel, wedging the stick upon the upper side to one-third of the depth, with slips of hard wood—at least in the extent to which we carried it—neither augmented nor impaired the ultimate strength of the timber, while it diminished its stiffness.

2. That the suspension truss, though it added to the stiffness, had no effect whatever, upon the ultimate strength, when only two bearing plates, (as b and c, Fig. 1.) were used, and the weight applied midway between them.

The reason of this appeared to be, that the deflection between the bearing plates, when added to the compression of the timber, at these, and at the abutments, allowed the beams to bend enough to exceed the deflection due to their elastic strength, before the suspension truss came fairly into action.

3. That the suspension truss, with a centre plate applied at a, Fig. 1, doubled the elastic strength of a plain girder of the stated dimensions, and added near fifty per cent. to its ultimate strength.

4. That trussing a girder with hard wood, in the usual manner, increased its elastic strength fifty per cent. and its ultimate strength about thirty-five per cent.

This last conclusion is nearly the same as that developed by Professor Barlow, in experimenting upon a similar truss. (See Treatise on the Strength of Materials: London, 1837, page 165.)

The experiments referred to, and of which we subjoin a synopsis, showed that though there was no efficacy at all, in a common girder truss, of three pieces of hard wood, with queen bolts,—indeed, that it was weaker than an untrussed stick,—still, the truss of two pieces, with a king bolt, similar to that of Fig. 3, did add considerably to the strength.]

Trussed or untrussed	Trussed.	Untrussed	Trussed.	Untrussed
Broken or not	Not brok.	Not brok.	Broke.	Broke.

Nos. 1 and 3 were trussed conformably to plate 39 of Nicholson's Carpenter's New Guide, the former being a model of a girder of 34, and the latter of 25 ft. span.

No. 1 was a *queen bolt truss, of three pieces*; No. 3 was a *king bolt truss of two pieces*, similar to Fig. 3, and the weights were applied in the centre, or over the angular point of the latter truss, and midway between the queen bolts of the former.

Hence it appears that whilst the queen bolt truss, No. 1, was actually weaker than the untrussed stick No. 2, the king bolt truss No. 3 was 33 per cent. stronger than the untrussed stick No. 4, of the same dimensions, and similarly strained.

Our experiments on model No. 5, which was trussed nearly in the same manner as Barlow's No. 3, display an *augmentation of 35 per cent.* over that of an untrussed beam.

The close agreement of our results with those of Barlow, probably justifies the declaration that—at least whilst they are new—the common wooden king bolt trusses add one-third to the strength of the girders to which they are applied.

Tredgold, however, in his invaluable treatise upon Carpentry, (2nd. Ed., London, 1828, p. 79.) says that "The methods in general adopted (for trussing girders) have the appearance of much ingenuity, but in reality they are of very little use." And again—"The defects of ordinary trussed girders are very apparent in old ones, as it is not simply strength that is required, but the power of resisting the unceasing concussions of a straining force, capable of producing a permanent derangement in a small surface at every impression."

As the tendency of time is undoubtedly to impair the efficiency of all sorts of trussing, and especially of those which—like girders trussed within their own depth—have *very obtuse supporting angles*; more extended experiments and farther observations are necessary to settle definitively the question of strength, between beams trussed within themselves with timber, and plain sticks of the same bearing, and scantling.

In 1828, Mr. J. Conder, soon after applying in practice the suspension truss of *two angular points*, (see Fig. 1.) seems to have become satisfied that it was defective; for he soon brought forward, as a great improvement, the idea of forming the truss with but *one angular point*, like Fig. 3, inverted; and it will be remembered, that in our experiments we were unable to procure any benefit from the suspension truss, until by the central bearing plate at *a*, Fig. 1, we had, in effect, reduced that truss to one of a *single angular point*.

In trussing a girder, the main object is to strengthen the weakest point—which is the centre of the beam—and as Barlow's experiments upon direct queen bolt trusses, and our own upon inverted or suspension trusses, of *two angular points*, indicated that no advantage was derived from either, when strained in the middle, we are strongly disposed to conclude, that whether the truss acts by tension or by compression, it should (in most cases) have but *one angular point*.

In support of this view, the writer may state that he has seen a number of suspension trusses of two angular points—attached to the girders of bridges—which, on close examination, indicated that they bore but little strain; whilst those with but one angular point, which he has had an opportunity of examining, seemed, in most cases, to be acting with much greater efficiency; this matter, therefore, seems to be of sufficient importance to justify our soliciting to it the attention and consideration of professional men.

Philadelphia, April 28th, 1842.

St. Rollox Chimney.—This chimney is now finished. This extraordinary work was constructed under the superintendence of Mr. Andrew Thomson, the able engineer. The extreme height, from the ground to the copestone, is 450 ft.; and, rising from a base forming the highest table-land of the city, the stalk is seen from a great distance in the surrounding country. In relative height, independent of the elevation of its base, it is little inferior to the loftiest superstructures in the world; in absolute height, it towers into the air incomparably higher. The great pyramid, Cheops, rises 498 ft., but this includes a base of 150. The Strasburgh Cathedral is 474; St. Peter's, in Rome, from ground to pinnacle, 450, being exactly the altitude of the *monstre* chimney; St. Paul's, in London, 370. The base of the chimney under ground is 46 ft. in diameter; at the ground 40; and at the top 13 ft. 6 in.

THE ROYAL ACADEMY'S TREATMENT OF ARCHITECTURE.

SIR—Neither "The Architect" nor "Ego Quoque" is, I suspect, the only one, by a very great many, who have cause to be dissatisfied with the manner in which architectural drawings are treated and disposed of by the Hanging Committee of the Royal Academy—to say nothing of the dissatisfaction given to those who go to look at, as well as to those who send, subjects of that class. Now, though I do not pretend to be able to suggest any "*reasonable excuse*" for that Committee or the Academy, their mode of proceeding being in itself altogether unreasonable and irrational, I can point out what I conceive would tend to abate, if not entirely correct, the inconveniences now complained of.

It is almost hopeless to suppose that the Royal Academy will reform any part of its system out of deference to public opinion. Your own Journal and many others have repeatedly animadverted on the very preposterous manner in which drawings are put up in the Architectural Room, many quite insignificant or uninteresting in subject obtaining comparatively good places, while others, far more worth looking at, are thrust where they can scarcely be seen at all; which is surely absurd enough, for if the space allowed to that department of the exhibition is so inadequate at the best, all the greater necessity is there that it should be turned to the best account—that the drawings admitted should be chosen with careful regard to their intrinsic merit and interest, and that since they must needs be comparatively limited as to number, they should also be select, and also still fewer than at present, no more being admitted than what can be properly hung up—that is, than can be properly seen and examined after they have been hung up. Frequent, however, as have been the complaints and remonstrances in regard to the utter want of good management with respect to architectural drawings, the Academy does not pay the slightest attention to them, doubtless because they are not brought before it in such formal manner as would render it impossible for some notice not to be taken of them. What I would, therefore, suggest is, that the Institute of British Architects should take up the matter in behalf of the profession, and formally communicate on the subject with the Royal Academy, urging the necessity for some reform and improvement in its exhibitions of architecture, and devising measures whereby such reform might be secured, as far as circumstances will at all permit. Let the Institute do this, the Academy would then be compelled to return some kind of reply; and however unsatisfactory the result might prove, at any rate the Institute itself would have shown a disposition to stand up for the interests of architecture and its professors, whereas the Academy's own professor of architecture does not seem disposed to interfere at all, but to leave the painters and the Hanging Committee to have it all their own way. I shall, no doubt, be told that what I have suggested is pretty much like the notable receipt for catching birds by putting salt upon their tails. I have proposed that the Institute should poke up the Academy; very good—but then who is first of all to poke up the Institute itself to do any thing of the kind. It surely cannot be required to be told that there is occasion for something being done in order to put the annual exhibitions of architecture upon a much better, and I may add, more respectable footing than they now are; and if the Institute has hitherto not thought fit to interfere in any way, though for such laudable purpose, is it to be imagined that it will do so now at the suggestion of any one else? Hardy! no matter; it must at least do one thing, disposed or not, for its silence will be equivalent to a tolerably plain avowal that it is determined to give itself no trouble, to listen to nothing proposed by others, more especially if what is so proposed does not immediately affect itself; therefore it must, at any rate, let it be seen with how much or how little public spirit and generosity it is actuated, and how far anxious to exert what influence it may possess for the benefit of the public and the profession.

I remain, &c.
CORRECTOR.

THE PROPOSED NEW CHURCH, KENTISH TOWN.

SIR—As Mr. Bartholomew expressed himself in his "Specifications" in no very measured terms relative to his brother architects, stigmatising the whole profession *en masse*, not only for their incompetence, but for various malpractices amounting to fraud, or what he terms *Fauitleroyism*, he has no right to look for much indulgence; nor can he reasonably be surprised if he now finds his own pretensions rather sharply scrutinized. Possibly he may be the only immaculate member in a profession in which—if we are to take his word for it—it would

require the lantern of Diogenes to discover an honest man in broad daylight; and so far he may be an honour to it. With that amount of praise, or rather self-praise, he ought, however, to content himself, for he is not likely to obtain much in addition to it.

Two lithographs have lately appeared, purporting to be an Exterior and Interior View of the Proposed New Church, Kentish Town, St. Pancras, inscribed "Alfred Bartholomew, Esq. F.S.A., Architect, Warwick House, Gray's Inn," which unusually minute piece of information looks somewhat too much like an advertisement or shop-card, were it not for the insertion of the "*Esq.*!" Still that is merely matter of taste, though too much à la John Britton, yet hardly in worse taste than the design itself, which is one of the strangest jumbles conceivable both as to style (Gothic) and as to the very inequality of character, for while in some respects it is ostentatiously showy, in others it is deplorably mean and insignificant. The exterior and interior are strikingly at variance with each other; the former—at least its front, looking at first sight more as if intended for that of a cathedral than of a moderate-sized church, while the interior is homely even to shabbiness, besides being, in point of design, hardly a degree better than carpenter's or Strawberry Hill Gothic. There is no unity of principle; nor does Mr. B. seem to have paid any regard to such economic management of the funds at his disposal or intended to be raised, as would have produced a tolerably consistent keeping up of character throughout. It now looks as if he had found out that nearly all the money would be required for the front of his building, scarcely any being left for the rest of it; he would therefore have done well to have retrenched from what now seems strange extravagance there, bestowed some decoration, or even some tolerable finish as to detail, where it is now evidently wanting, and that in a very disagreeable degree. If instead of two towers and spires, he had contented himself with one, he would have been able to bestow some panelling on the fronts of the galleries, and to pay more attention to detail generally within the building. Neither would the exterior itself have suffered by such retrenchment, for at present the front seems too crowded up and overdone; and the little projection—apparently intended for a vestry—between the porches in the lower part of the towers, is a feature that, so far from agreeing with the rest, either as to style or anything else, is no better than an eye-sore, and looks paltry in itself, and throws the whole out of keeping. As to keeping, however, that seems to have been scarcely attended to at all; for as far as the side which is seen can be made out, thrown so much as it is into perspective, the front is a mere mask to the rest, the character there aimed at being carried on no farther. In fact, as shown by the interior view, the side windows have neither mullions nor tracery, but are mere holes in a wall, and that none of the thickest. Whether it be owing to bad drawing or not—and the perspective at least is strangely incorrect—the whole of the interior has a very disagreeable look, it being not only very plain, but remarkably poor in character, with at the same time a good deal which is fantastic—for instance, the small round windows over the pillars that support the arches. The whole, in short, has a singular, meagre, starved appearance, altogether different from that sober style which might excuse or might readily be excused by economy. If such very rigid economy is thought necessary for this part of the building, why is there so much tawdry parade and pretension in the exterior? It is surely not at all in accordance with what either judicious economy of design, or the commonest rules of good taste, would dictate.

No doubt my remarks will be thought no more agreeable and liberal in feeling by Mr. Bartholomew, than were his own wholesale aspersions of the profession, by his brother architects. Still they are such as he may profit by, unless he should find, upon further consideration, that he can really produce nothing better than this lame abortive design. At all events he will perhaps now learn to speak with a little more reserve if not respect of others, since he has certainly not shown himself to be at all superior to them in talent.

I remain, &c.

AN ARCHITECT.

THE INSTITUTE AND ITS TRANSACTIONS.

SIR—Since no notice was taken of it in the review of the "Transactions of the Institute of British Architects," allow me to make some comments on what struck myself most forcibly, on looking at the title-page. I mean the appearance of Messrs. Longmans' names as the publishers. I have nothing whatever to object to that highly respectable house, and had they been appointed publishers in the first instance, no exception could have been taken at it; but it does look like an exceedingly strange "transaction" on the part of the Institute,

that they should have taken the work out of the hands of its first publisher, and placed it elsewhere—that publisher being one who is in a manner identified with the architectural profession, who has done so much in undertaking and bringing out works that might else never have appeared, and who is therefore justly entitled to all the countenance and support the profession as a body can show him.

Putting aside all reference to that individual, it certainly does seem—to myself, at least—very ungracious and impolitic in that body which represents—or would, in the eyes of the public, appear to represent—the architectural profession and its interests, to withdraw from Mr. Weale almost the only compliment they could show him; more especially after receiving from him as presents, from time to time, books to which it would have become them to have been subscribers and purchasers! Call you this backing your friends? Is this the way to promote enterprise in a branch of publication which, standing as it does upon a very different footing from that of general literature, requires more than ordinary encouragement from those whose studies are aided by it? Probably the Institute may have made a "better bargain;" by acting as they have done, they may have saved, or else they hope to get, perhaps, a few shillings extra. Perhaps—for there is room now for any suspicion—they tried every publisher in town, from Burlington and Great Marlborough Streets to Finch Lane, or farther, if a "farther" there be, before they entered into treaty with the "Row." The advantage they have gained ought to be great, for great is the paltriness of having even thought of seeking for it. But though the odium of the "transaction" falls upon the Institute, I do not imagine it met with the concurrence of all or even a majority of the members. At least, I know one or two who look upon it in pretty much the same light as I do myself.

Dismissing this matter, I have to remark that, as far as the volume itself is concerned, there is very little in it indeed to identify it with the Institute, or which manifests any of that co-operation to be expected from a body established, it may be presumed, to effect what the zeal and study of individuals cannot pretend to accomplish. What we obtain from it is altogether the result of private study and individual diligence; and one of the most valuable papers in the "Transactions" is a contribution from one who is not a professional architect. Very far am I from complaining at meeting with papers of that class, the acceptance of which is rather creditable than otherwise to the Institute, because it shows liberality of feeling towards amateur students. What I complain of is, that there is nothing to show either what the Institute has done, or what has been done in architecture, during the time it has been established, and since the publication of the first portion of its Transactions. There are no official documents or records of any kind; no official report upon the chief of the very numerous buildings erected or undertaken during that interval, both in this country and upon the continent; no extracts from the correspondence of foreign members, nor any authentic information so derived; no notice of foreign publications presented to the Institute—I do not mean critical notices or reviews of them, but simple statements explaining their contents. Nay, there is not a single record of the briefest kind of any of the more eminent men in the profession who have died within the last five or six years, either British or foreign. Wilkins, Wyattville, Rickmann, Foulston, Albertoli, Antolini, Schinkel—some, if not all, members of the Institute, have within that period terminated their earthly labours; yet not one syllable of record has been bestowed upon their memories or their works, by the Institute whose "Transactions" are in that respect, and not in that respect alone, a complete blank. After this let us hear no more of the public indifference to architecture, when even the Royal Institute of British Architects shows itself to be infected with almost inexcusable apathy. The members and council of the Institute would do well to recollect, that though they themselves may choose to shut their eyes to what ought to be done by them for the advancement of architecture as a liberal study, they cannot hinder other people from opening theirs, and keeping awake to them and their proceedings.

I remain,

Yours, &c.

A GREATER ADMIRER OF ARCHITECTURE THAN OF THE INSTITUTE.

REMARKS ON THE CLAIMS OF ARCHITECTS.

SIR—The first two articles in the August No. of your Journal tempt me to make a few observations; for although the remarks therein are no doubt generally good and useful, they certainly do appear to me rather too sweeping and unqualified.

In the first article, the merits of the Threadneedle St. structure (and

I suppose its novelty is considered as not its least merit,) serves as a text for enlarging on the demerits of almost every thing in the way of architecture that has been done of late years, in the metropolis at least, and of underrating Grecian architecture in particular, as if it were responsible for all the abuses of mere builders, decorators, would-be architects, and, it cannot be denied, of some from whom, as architects of high standing, we might have expected better things; and I can only account for *their* failure by supposing them deficient in that natural taste and feeling for the art which is indispensable to a successful exercise of the profession.

I must, however, beg to differ entirely as to the facilities which "Stuart's Athens" in particular affords for producing Grecian designs, as I do not see how this publication can supersede or render unnecessary study and invention, more than publications in any other style; and I think it may be found that Mr. Barry himself, who deservedly stands pre-eminent as an architect, has *his* book of reference, too, and that the most prominent features of detail in his best designs might there be found delineated. It is not, then, the use of this or that style, this or that order, moulding, or ornament, which constitutes a good or bad design, but the spirit and mode in which they are applied and dealt with; and there can be no more good reason for rejecting any of the materials of design which former ages have produced, especially when of acknowledged beauty, than of shunning the letters of a language because they have been used over and over again, and for the commonest purposes. There clearly, then, must be materials to work with; but I think it cannot be doubted that to natural taste alone, which can neither be learnt nor unlearned, is owing those superior productions in architecture, which so few can boast of the opportunity of displaying. To afford the facilities for embodying and bringing before others, those treasures of the mind which one individual possesses over another, a suitable education is, however, necessary; and 'tis impossible (I think) to conceive it can be carried to excess.

The orders of architecture, as found in Greece, (not Rome,) are indeed beautiful, but they will not bear being trifled with; he, therefore, displays most taste and judgment who, instead of endeavouring to drag them in on all occasions, rejects them altogether, unless he can place them in a situation befitting their high rank: for we can well perceive, by the ancient examples, how much sublimity and grandeur they are capable of producing, not, however, by the Italian method of first degrading them in detail, and then forming separate pieces of columnar design, for mere ornament, to doors or windows, as exemplified at the Travellers' and Reform Clubhouses, but by making them primary and useful parts of an edifice.

The remarks in the second article, headed "Spirit of Architecture," are, some of them, so extraordinary, that I am rather doubtful whether to treat them seriously or not. The London architects will, I am sure, have no reason to be proud of some of them, and if any, or even the majority, are deserving of them, 'tis hardly fair to include the whole; it would be much fairer to allude to the particular parties, or at least their respective works. There are architects, however, elsewhere than in London; and I think I could point out some examples of design in distant parts of England by native architects, that would induce even the severe author of "Spirit of Architecture" to pause in his denunciations, especially when contrasted almost side by side (as in some places they may be) with such productions of eminent London architects as alone can justify that author's severities.

I never before heard of architects altogether disregarding public opinion, when not expressed in such absurdities as whitened towers and churches, roughcast sculpture, and reddened plaster fronts. Indeed, to show that discretion requires to be used in yielding to public opinion, I myself have heard one of that public (and one, too, who had travelled) seriously suggest as an improvement that a certain public building should be painted red, and scored in imitation of bricks; and yet the paper quoted seems to say that the *uncultured* mind is not only a more fitting judge of architecture, but would make a better architect than such as have spent a life in its study and exercise. Such remarks, however, are innocent enough, inasmuch as they overshoot the mark; but, for the same reason, they must fail of doing good, which should be the object of all criticism.

How an architect can be too architectural, or too strictly educated, I really cannot conceive; 'tis, I fear, far too likely, in most instances, that the fault is that of deficiency; although, as I said before, education can neither bestow nor take away that natural taste and talent which enables an architect to excel: and to these gifts of Nature was perhaps owing that eminence in their day of those interlopers, as they are called, Michael Angelo and Sir Christopher Wren; to neither of whom, however, are parties agreed now-a-days in attributing the highest excellence as architects. The praise, too, bestowed on the latter in the "Spirit of Architecture" stands in rather awkward juxtaposition with the observation in the former article, where, in alluding to the

ugly churches of London, it does not except "the more *admired* than admirable ones by Sir Christopher Wren."

If architects' duties really are passing away from them to civil engineers and decorators, that surely must be the fault of the employer, not the employed; and it would be a slur indeed on public taste and discernment to imagine for a moment that, until they have searched Great Britain to every corner, they should have recourse to civil engineers or builders, the former being almost proverbially incapable of strictly architectural productions; while, on the contrary, architects, if educated as they ought to be, must be equal to all an engineer's duties, which they do and will perform, when prejudice does not prevent their being called on. From builders no one, I believe, ever expects anything like architecture; and those who do permit them to unite the offices of architect and builder too not only show themselves careless of the merits of the production as a work of art, but must find, too late, that they thereby deprive themselves of that salutary check on the builder, which it is part of the architect's office to afford. And as for *decorators*, my little experience teaches me that they have happily much less controul than formerly. The Reform Clubhouse is not the only nor the most decided instance on which I found this observation; and, depend upon it, it is almost invariably the employer's fault, either through ignorance or custom, if ever the decorator, or any other pretender, is allowed to interfere with any part of a building which has to do with its effect in the minutest particular. Much more might be said on these subjects, but I leave it to more able although not more zealous friends to architecture, and merely state, in conclusion, that, instead of issuing such sweeping denunciations, it would, I think, be a far more useful plan to bring forward, analyze, and compare the several examples of architecture separately, with a view to ascertain their merits and demerits, as such.

Aug. 11, 1842.

AN ADMIRER OF ARCHITECTURE.

[We are at a loss to understand wherein lies the iniquity of contrasting the Threadneedle Street structure with other London buildings, and indeed we do not very well see by what means its relative merit could have been estimated, but for some such species of comparison. We have never held Grecian architecture answerable for the faults of those who occasionally misapply it, nor is it the use but the abuse of Stuart's Athens we have ventured to reprehend. Such works we admit may, perhaps, be perused as diligently by Mr. Barry and other men of merited celebrity as by the most notable imbecile of the confectionary faction; but we suspect that in the one case the designs are received merely as suggestions, in the other as the responses of an oracle; and it is scarcely necessary to remark, that it is the latter species of appropriation we have alone reprobated.]

We pass over several of our correspondent's observations, and hasten to state that we have never maintained mental cultivation to be unfavourable or even unimportant to architectural proficiency, *provided the cultivation be of the right description*, but that there is a species of cultivation productive only of weeds, and fatal to every germ of genius, nature may have implanted. It is a familiar enough remark that wherever schools of art flourish, the arts themselves decline; and if it be the property of the prevailing system of architectural instruction to discourage the growth of the natural emotions and create others that are peculiar and artificial—to superinduce an irritability of taste respecting petty observances, and a disrelish of the ordinary beauties of ordinary minds—to quench all natural sensibility of heart, and impose upon the judgment by the authority of a senseless jargon—to eradicate nothing but taste, imagination, and genius, and foster nothing but mannerism, affectation, and formality; if this, and more than this, be the general tendency and general effect, too, of the existing modes of education—and all because they are too technical, stringent, and specific—it is easy to understand how the education of an architect may be too architectural and his taste less true than tastes less systematically perverted. Education can never create taste, but may ennoble or debase it according as the education is in a right or wrong direction; and the prevalent direction in the case of architecture is, we conceive, such as to be generally productive of unfavourable influences. From such influences the architects of ancient Greece were in a great measure exempt; they girded on their armour and went forth with their fellow citizens to the battle—they listened to the discourses of the philosophers, and mingled in the assemblies of the people, and shared in the anxieties of the commonwealth, and partook of the responsibilities of the administration; they felt not as architects merely but as men—their associations were not the associations of a sect or individual, but of the community, and their beauties derived not from Egypt nor Phœnicia but from Nature. Had they, like us, been content to be servile copyists of exotic constructions or pedantic retailers of authoritative dogmas—had they, like us, assumed that another people had, by some happy intuition, found out the only forms in which beauty could be embodied, and that nothing was left for them but to multiply and combine those mysterious proportions—they would never have risen beyond the limits of mediocrity, and the world would have

been deprived of the delight, and themselves of the glory, their more adventurous career has so bounteously conferred.

The insinuation that it is a distinction of the popular taste to entertain an affection for rough cast sculpture, is one of those inoperative libels which finds its refutation in its own extravagance; and as regards the other proofs of the depravity of the public predilections, it is sufficient to say that we think them singularly inconclusive. A whitened tower may be a very picturesque object in some situations, and if it be true that a brick wall may be less displeasing than an architectural abortion, the recommendation to imitate brick in a certain public edifice may, for aught we know, have been far from injudicious. It is rather a novel doctrine, we think, that if a man's business passes away, it is necessarily the fault of his employers, and never of himself; but however consolatory such a conviction may be, we fear it will be found to be a poor indemnity for so serious and substantial a deprivation. We agree with this gentleman in thinking that men excel in architecture by virtue of a "natural taste and talent," but are unable to reconcile this with the declaration that engineers and decorators are necessarily incapable of architectural productions. It is difficult to imagine that nature reserves her taste and talent for architects exclusively; and if a fair proportion be distributed among engineers and decorators, those of them to whom this qualification falls, ought, by our correspondent's own canon, to be perfectly capable of architectural excellence. We agree that the architect is a salutary check upon the builder, and the value of this check the public is well able to estimate. The praise and reprehension of Sir Christopher Wren may appear to stand awkwardly together in our pages, yet both may we conceive be perfectly just; and the awkwardness will we suspect appear most conspicuous to those who will not understand that an extensive edifice or multitude of edifices may afford matter for just ridicule and just commendation, and that the genius of an artist however great, may still be liable to some exceptions. It would have been quite foreign to the purpose of the spirit of architecture to have entered into the details of architectural composition, or compared one building with another, with a view to ascertain their merits and defects; and we think the title even of that paper is enough to show that its concern was not with the details and specialties of architecture, but with its radical and universal principles. Any remarks upon such a subject must necessarily be sweeping, simply because they are general; and we think it rather an extraordinary course to object to its strictures, not because they are unjust, but merely because they are not personal.—*EDITOR.*]

REVIEWS.

Transactions of the Royal Institute of British Architects. Vol. I. Part 2. London: Longman & Co., 1842.

(Concluded from page 260.)

THE paper by Herr Hallmann, of Hanover, on the Greco-Russian Ecclesiastical Architecture, is a valuable contribution. As an historical essay, and an exponent of manners and customs relative to the Greek church, it will be perused with interest by all classes of readers, while to the professional architect, it affords a new and instructive study on the great radical principle of his art—the adaptation of the arrangement and character of an edifice to the especial purpose for which it is destined. A comparison of the Greek and Romish ecclesiastical edifices, for which, as regards the former, this essay affords ample materials, cannot fail to impress strongly upon the mind of the British architect, that the study of combinations differing from both is demanded of him by the ritual of the Reformed Catholic Church of England. It is difficult to conceive any thing more repugnant to reason and sound taste, than the recurrence, in these days, to ecclesiastical arrangements peculiar to the worst form of superstition and priestcraft that ever degraded the Christian community; and yet such is the style of planning churches loudly called for by ignorance and intolerance at the present moment, and dignitaries of the establishment are not ashamed to prostitute the influence of their station by joining in the cry, under a Jesuitical pretence of encouraging architecture. But to return to our immediate subject. After a prefatory historical sketch of the progress of ecclesiastical architecture in Russia from the tenth century, Herr Hallmann proceeds to describe the plan, arrangement, and decoration of a Greco-Russian church. To follow this description connectedly would be to transcribe the bulk of the paper; we shall, therefore, be content to extract so much as relates to the principal feature of the interior—the Iconostasis, or screen separating the sanctuary from the body of the church. It is probable that many who may have had the opportunity of seeing Greek churches, may not be aware of all the mystical intention of their ornaments:

"A perfect Iconostasis is the representation of the universe, or rather of the celestial kingdom. It is composed of four or five different tiers, four of which are indispensable, as will be presently explained. Each tier is composed of an unequal number of pictures of saints, painted on tablets or long square surfaces, the position of which is rigorously fixed.

"On the first tier, which rises generally a few steps above the ground, (the number of steps is indifferent provided they do not exceed seven) are three doors; the middle is a folding door, by means of which a view of the altar is obtained during the ceremony, and is ornamented with the Annunciation of the Virgin, the Virgin on one of the leaves, and the angel on the other, accompanied by the heads or emblems of the four evangelists; on the right is the effigy of Christ, on the left that of the Madonna—on the right after that of Christ, is placed the picture of the saint or of the festival of the church—then come the smaller doors already mentioned, which are single doors. Above the central door there are occasionally three angels' heads, as symbolical of the Trinity; above the smaller doors are placed, on the left the Greek cross, on the right the cross of Moses, symbols of the new and old dispensations. Such are the indispensable arrangements of the first tier; if there be more room, it may be ornamented with other pictures of saints. Of these principal pictures only the heads, hands and feet are visible, the body is covered with a metallic clothing or drapery of silver or gold in very flat relief—the ground, like that of the whole Iconostasis and often of the entire church, is gilt. Before each picture a lamp is suspended exactly in the middle, and the pictures ought not to be higher than to allow of kissing at least the feet.

"On the second tier Christ is represented in the middle, seated on a throne, clad in pontifical robes. On the one side is St. John the Baptist, on the other the Madonna without the child—after that appear on each side two archangels and six apostles; the different tablets upon which these effigies are painted, seem in the ancient churches joined to one another without ornament—in the more modern they are divided by little gilt columns.

"On the third tier we find the Madonna in the middle seated on a throne, holding the infant Jesus on her knees; on each side of her are seen the effigies of the prophets.

"On the fourth tier God the Father is represented on his throne in the centre, with the infant Jesus—on each side are the patriarchs of the church; on this last tier the effigies are surmounted by small arches, the centre one being higher than the others. As the figures in the middle are seated, they are twice the size of the others which are standing. Sometimes there is a fifth tier, which is placed either between the first and second, or between the second and third; and upon the tablets of this tier are representations of the history of the Saviour, the last supper, the passion, the crucifixion, &c.; this tier is generally only half the height of the others.

"It remains yet to be mentioned that on the vault of the great cupola before the iconostasis is generally painted an enormous head of Christ, and that a great lustre nearly touching the iconostasis is suspended before it.

"The other parts of the church are ornamented with paintings on a gold ground; even the columns are decorated in this manner; but all these paintings represent miscellaneous subjects. In style they are wretched, and perfectly resemble the art of the early Christian ages. The church is lighted generally by very narrow windows, perforated in the side walls, or in the drums of the cupolas; for festivals there is a great display of lustres, made of plated copper, which hang from the vaulted roof. The general internal appearance of the Greek churches is on the whole extremely solemn and imposing on account of their magnificence and mystic aspect."

The Institute showed their sense of the merit of this paper at the time it was read, by presenting a silver medal to its author. The editors of the volume have done him less than justice as regards the illustration of his work. There are two general plans and one elevation, and six specimens of Russian cupolas, crammed into one quarto plate, and the plans especially are so small as to be nearly useless. A second plate represents an Iconostasis on a better scale.

The "Report of the Committee appointed to examine the Elgin Marbles" in order to ascertain whether any evidences remain as to the employment of colour in the decoration of the architecture or sculpture, will require little observation, since it was printed entire in the last No. of the Journal. It is in one sense a most satisfactory document, since it sets at rest for ever all question as to what traces of colour may or may not exist upon the marbles subjected to examination.

This report concludes the first portion of the volume, comprised under the general head of "Antiquities." The first paper of the second part, coming under the head of "Construction," contains some very important statistical facts on the cost of certain public buildings abroad, chiefly at Berlin, communicated by Herr Beuth, of that city, honorary and corresponding member of the Institute. Many of the buildings particularized are published in Schinkel's "Architectonische Entwuerfe," so that the proportionate expense of building in Prussia and England may be easily deduced from the information furnished by Herr Beuth. By a schedule of prices for labour and materials, it appears that the former may be obtained in Berlin for less than half its cost in London, measured brickwork for about two-thirds, and timber for little more than one-fourth. These rates must be kept in mind in

estimating by the sums total the scale of liberality on which the modern public buildings of Prussia have been erected. It appears that the sum of £47,583 has been expended on the new church at Potsdam, £94,810 on the Theatre Royal at Berlin, £30,879 on the School of Royal Architects, &c.

Mr. Gwilt's "Observations on the Weight of Entablatures" refer to the proportions between the supports and the mass supported, in the orders of architecture; and he shows a probability that the proportions assigned by the ancients to their columns and entablatures, may be founded on a principle of making the area of the mass supported, taken on the geometrical elevation, equal to that of the supports, and the voids, or intercolumniations, equal to the amount of both. It is clear at first sight, that these conditions are fulfilled by any colonnade, where the intervals are systyle, and the entablature somewhat more than one fourth of the height of the column, proportions which are very nearly observed in the best works of antiquity. The rules laid down by Vitruvius tend to the same point, and Mr. Gwilt's position is further strengthened by the actual measurements of some of the ancient temples which he has compared in a table, though others are rather wide of the mark. It is impossible to suppose the coincidences which occur to be accidental, but they will scarcely bear out a general rule, which, to be worth any thing, ought to be of general application. The effect of such a law in architecture would be, to increase the load in proportion to the diminution of the support. It is obvious, that as the height of any series of supports of given diameter is increased, and their strength consequently diminished, both really and apparently, the intervals between them increase in area, and so therefore must the superincumbent mass be increased in order to fulfil the conditions. It is true that *within certain limits* this is the actual practice of the ancients. A Corinthian entablature one-fourth of the height of the column, is a greater proportionate load than a Tuscan entablature bearing the same relation to its support, (the intercolumniation remaining the same). This apparent anomaly has been very well explained by Sir W. Chambers, and we object to Mr. Gwilt's view of the subject, only because it is too sweeping, and because we think he ought to have taken the limits of the ancient practice into the account.

We do not understand the author's mode of dealing with the pediment. The diagrams on this subject require explanation; they seem to represent the entablature diminished in height until the addition of the pediment makes up the required mass; but we are not aware of the existence of any such practice either in ancient or modern composition. Nor can we discover by what process the voids in the portico of the Pantheon are made out to be equal to the solids, as stated in a postscript by Mr. Cresy, especially as these proportions are set down very accurately in the preceding page as 1.84 to 2.43. It must be observed that Mr. Gwilt does not by any means insist upon this part of the theory, but as regards the proportions between the supports and the weights, he considers that there is every appearance of its being strictly true.

The next paper in order is on "Lithology," or observations on stone used for building; by Mr. C. H. Smith. Mr. Smith, it is scarcely necessary to remind our readers, was a member of the Commission appointed to survey various quarries throughout the Kingdom, for the purpose of selecting stone for the new Houses of Parliament. The information resulting from this inquiry has found its way to the public in several shapes, but in none more likely to be of general practical utility than the able and well digested performance before us. The author treats principally of those extensive and useful classes of stone, the sandstones and the oolites; but we must rather call the attention of our readers to the pertinent remarks which occur on the consequences of want of attention on the part of the architect to the quality of the materials offered for his use. The effects of this negligence are particularly to be noted in the metropolis, where all stone must be brought from a distance, and where even the most inferior is scarce and dear. Mr. Smith shows that of Portland stone, so much in request in London, there are numerous shades of quality, dependent mainly on the position of the bed from which it is raised, and partly from the variation in the corresponding beds in different localities, and yet this circumstance is scarcely ever considered in selecting the material. Portland stone is Portland stone, and the architect is too ready to accept it as it comes to market.

"I have carefully looked over," says Mr. Smith, "many specifications for public and private buildings, and find the materials usually described to be of the best quality; but the general tenour of those parts describing the stone to be used rarely amounts to anything more than the mere well-known name, preceded by an adjective, such as 'good Portland stone,' but what is to constitute that 'goodness' is altogether undefined.

"Large quantities of Portland stone of an inferior quality are brought to London, not because the island is deficient in the best kind, but because all

our large buildings are executed by contracts, at so remarkably low a price, that the mason's study is not what kind of stone will be most durable, but what stone can be wrought by the workmen most expeditiously, and thereby yield the largest profit; and of course the proprietor of the quarries will only send such stone into the market as is likely to suit his customers. St. Paul's Cathedral, and many of the churches and other large buildings, erected in the reign of Queen Anne, were constructed with stone very superior, as far as regards durability, to the greater quantity now used; and yet the quarries from whence those sources were derived have been deserted beyond the memory of any inhabitants now living at Portland; and the only reason assigned is, because the merchants find they cannot sell such stone, on account of its being a little harder, and thereby more expensive to work."

"Abundant examples of defective Portland stone might be pointed out; but when we consider that the stone brought from the island, good, bad, and indifferent, is all shipped from the same pier, which is a very small one, and that notwithstanding the blocks are marked in the quarry, so as to denote from whence they were obtained, it is possible that some of them may be misplaced, we ought not to be surprised if occasionally a very bad stone is conspicuously placed in a building that is otherwise in excellent condition; and this we find more particularly to be the case in our modern structures, arising no doubt sometimes from ignorance or inattention, but often from some trifling interest, such as using a stone because it is just of the dimensions required."

"There are not fewer than fifty or sixty quarries already opened at the Isle of Portland, most of them along the north-east and north-west cliffs, at an elevation of several hundred feet above the sea. The stone from each of these quarries, and from different beds in the same quarry, almost always presents some minute particularities, which, on very attentive examination, will serve to distinguish it from others. In many instances these distinctions are so conspicuous as to be evident on the most casual inspection."

Bath stone is brought to the London market under precisely the same circumstances.

"The principal quarries are at Box, Coombe Down, and Monkton Farleigh. The stone from each of these districts, and even in the same quarry, where there are generally a number of beds lying upon one another, is frequently found to differ, in some of the minor characters, from all the rest; such as being harder, coarser, more or less durable, &c., all of which are indiscriminately sold in the markets under the general name of 'Bath stone,' and it rarely happens that an architect specifies what kind of Bath stone is to be used. It is always understood that the materials are to be good, or of the best kind; and it unfortunately too often happens that the stone which looks best when fresh from the workman's hand, is frequently of a description most subject to premature decay. If it be left to the mason's choice, he is sure to select the stone that may be most expeditiously worked."

Bath stone finds little favour with our author, who disposes very satisfactorily of the common notion that it stands better in its native air than when exported to a distance.

"The plain matter of fact is," says Mr. Smith in his plain matter-of-fact style, "that the stone used in the construction of the oldest buildings at Bath was procured from the Box quarries, which is in the more important qualities very superior to and far more durable than such as is now generally used. The Box quarry stone is still used occasionally in and about Bath, but the stone merchants in London have long since discovered that the masons will not buy it on account of its being a little coarser and harder, and thereby more expensive to work."

Two other vulgar errors on the same subject are also noticed. Speaking of the decay which is already manifest in the restorations of Henry VII.'s chapel, Mr. Smith observes as follows:

"That there are many stones in the building which at present show no symptoms of decomposition is readily admitted; and those persons who advocate the use of Bath stone for such highly decorative purposes, frequently imagine that sufficient care has not been taken to place the stones on their natural bed. The importance of such precaution is generally very considerably overrated; I do not consider it signifies which way a stone is fixed, unless it presents a decidedly laminated structure, which scarcely ever occurs amongst the oolites. A stone of an open, powdery, and slightly cemented texture, will, if exposed to the weather, decompose in a comparatively short space of time, in whatever direction it may be fixed, or whichever surface may be parallel to the horizon.

"Another generally received fallacy is the opinion that soft stone will become hard and durable by exposure. Although this notion is true to a certain extent, it is not of sufficient importance to warrant its appreciation in architectural works. All kinds of stone while in the rock, or when recently quarried, are somewhat softer and more easily worked than after they have been exposed to the atmosphere a few months, owing to the stone in its original situation being more thoroughly saturated with moisture that can ever be accomplished after it has been once allowed to get dry. This is a principle well known to masons, for it is a general practice amongst workmen to frequently wet a stone, especially if it be rather of a hard quality, during their operation of working it into mouldings or ornaments, to make it work, as they term it 'more kindly.' If the stone be remarkably soft, it is advisable not to let it dry too fast after it has been taken from the quarry,

for fear of its cracking, in consequence of the moisture being removed from the outside before the interior of the block can have had time to evaporate; hence, while the central part remains of its original size and extremely damp, the surface will dry, shrink, and thereby cause many invisible cracks, the effect of which will be conspicuous after a sharp frost.

"All free-working limestones and oolites become in some degree harder on their surface by exposure to weather. This arises from a very slight decomposition taking place, which will remove most of the softer particles, and leave the hardest and most durable to act as a protection to the remainder. In addition to which, the pores and interstices of the surface get filled with dust and dirt, washed in by rain assisted by powerful winds; all which circumstances help to secure the least protected grains from external violence. If the stone be naturally compact and durable, a surface of this description will materially assist its duration; but, on the other hand, such material as the Heddington stone, near Oxford, or the most perishable Bath stone, will in due time similarly attain a hard crust, which, from the general body of the stone being loose and powdery, is not sufficiently compact to hold on; water will soak in behind the crust, cause a swelling and disruption on the surface, which ultimately breaks. The crust thus opened gradually bends forward more and more, until finally the weight of the disintegrated portion causes it to fall off. In some instances, as in Bath stone, these defective places rarely exceed an inch or two of surface before the decomposed part falls off; whereas the crust of the buildings at Oxford is so remarkably tenacious that it peels off and hangs like rags, often as much as a foot superficial, before it entirely separates. Upon the whole, I do not consider it a recommendation to a soft stone to say that it gradually becomes harder on the surface."

We must take leave of this paper, from which we are tempted to continue our extracts to a greater length than might be advisable. It is illustrated by a map of the Island of Portland, and a section of the strata from which the stone is raised. It concludes with some observations on M. Brard's process for testing the qualities of building stone by disintegration, which Mr. Smith holds rather cheap, as not being supported by established physical truths, that is to say, by the effects observed to have taken place in the same kinds of stone by long exposure in old buildings—Barnack stone, for example, which remains generally in the highest state of preservation in Peterborough Cathedral, and other buildings in the neighbourhood of the quarries, disintegrates rapidly under the process, while others which stand high for durability under this test, are found to have suffered severely from the slow tooth of age.

To Mr. Fowler's paper "On warming and ventilating the long room of the Custom House, London, upon Dr. Arnott's principle," we have but little to say. The practical application of a familiar principle is precisely one of those subjects best calculated to occupy profitably the time and attention of an evening meeting, and had we experienced the pleasure of hearing this paper read on such an occasion, we could have complimented the honorary secretary very sincerely on his production. But for its place among the transactions it has probably been indebted to its illustrations, which exhibit the only specimen of original design with which the Institute have favoured us. The composition in the second plate being quite unconnected with the practical part of the subject, it is to be presumed, from the extraordinary distinction with which it is treated, that the Society are proud of it. We must confess we would rather the same breadth of copper had been bestowed upon Herr Hallmann; but this, as the upholsterers say, is a mere matter of taste, and we hint an opinion upon it with extreme diffidence.

The concluding paper is a report on the construction of the stone arch, (or, according to popular designation, "stone beam,") which exists between the western towers of Lincoln Cathedral, by Mr. Nicholson, accompanied by an engraving, made from very careful measurements. This arch, which is an object of curiosity from its extraordinary flatness and lightness, consists of 23 stones of unequal lengths. The width of the extrados is barely 1 ft. 9½ in.; the thickness of the arch is uniform throughout, and is 11 in.; the span 27 ft. 11 in. between the apparent abutments, but as the walls on both sides have been cased since the arch was built, the original span is 30 ft. The arch having settled into a somewhat irregular shape, doubts have arisen as to the nature of the curve; but Mr. Nicholson's minute investigation decides it to be a pointed arch, drawn from two centres, the chord of the southern arc being 13 ft. 11.664 in., and its versed sine 2½ in.; and the chord of the northern arc 14 ft. 0.234 in., and the versed sine 2½ in.

The object for which this singular structure was erected is a mystery, and Mr. Nicholson considers it in vain to offer any conjecture as to its purpose. Mr. Papworth, however, suggests in a postscript, that it might have been set up at the time when the vaulting of the nave was built, as a fixed point from whence levels and measurements might be taken.

We now conclude our lengthened notice of this volume, with an earnest hope that the Institute may speedily be in condition to lay

before the public another, equally instructive, entertaining, and ornamental. We can bestow upon them, at parting, no better wish.

Appendix D to the new edition of Tredgold on the Steam Engine and on Steam Navigation. On the Archimedean Screw, or Submarine Propeller. By ELIJAH GALLOWAY, Civil Engineer. London: John Weale, 59, High Holborn. 1842.

THIS is a work which does Mr. Galloway great credit, and which, we venture to predict, will be received by engineers most favourably. The subject is itself one of great interest, and Mr. Galloway has treated it in a very perspicuous and business-like manner. He evidently understands what he talks about—has studied it deeply and well—and has the art, moreover, of stating what he knows in clear, concise, and not inelegant language. Our inquisitorial office would speedily become a sinecure, if we had none other than such books as this to deal with.

Mr. Galloway first gives us a short historical account of the Archimedean screw as a propeller, from which we extract the following passages:—

"In a work on the theory of the screw of Archimedes, published at Paris in 1768, by M. Pauton, the following passages occur:—

"The oar is an instrument by means of which we are enabled to move a vessel on the surface of the water. It is a long lever, terminated by a flat end, by the pressure of which upon the fluid an operation similar to the action of a wedge upon wood is produced. The *point d'appui* of this lever is the pin to which it is attached; the moving power is the rower; and the resistance is the fluid: which is, however, contrary to the opinion of some writers. I am surprised that no one has thought of changing the form of the common oar, it being evident that it is not perfection. In effect, besides that the action of the rower is not calculated to make the vessel advance equally, because the oars describe arcs of circles in their movement, the rower is obliged at least to employ a moiety of his time and strength to lift the oar out of the water, and carry it in advance. To remedy this inconvenience, it would be necessary to substitute for the ordinary oar an instrument the application of which would be if possible uniform and continuous; and this property will, I think, be found in perfection in the *ptérophore* (the Archimedean screw). We should be able to place two of them horizontally and parallel to the vessel's length, one on each side, or one only at the fore part. The *ptérophore* may be entirely immersed, or up to the axis only, as is desirable. The size of the *ptérophore* will depend on that of the vessel, and the curvature of the thread on the velocity with which it is proposed to row."

This is, perhaps, one of the earliest notices of the screw as an instrument of propulsion since the revival of learning, but it appears to have been in use among the Chinese for that purpose from time immemorial. Some of the schemes of propelling by means of a screw, which drew the public attention about thirty or forty years ago, were simply importations from China. Mr. Galloway quotes some certificates, with the view of showing that the screw had been introduced in some of our Government vessels as an auxiliary means of propulsion as early as 1802, and that the models of the plans then adopted were subsequently examined and approved of by Mr. David Napier—than whom there are few better judges in all such matters. He then recapitulates the statements of Marestier in his work on American steam navigation; the projects of Brown, the inventor of the gas vacuum absurdity; and the speculations of Tredgold, which are shown to be in many respects erroneous; after which he comes to the era created by the achievements of Mr. Smith, to whom, we conceive, any success this mode of propulsion has realized is mainly attributable. The structure and performance of the Archimedes are next minutely described: with these details many of our readers are already conversant; and those who are not so we must refer to Mr. Galloway's work, as no abstract would be useful, and no abridgment would be right. Of Ericsson's propeller, shown in Figs. 1 and 2, we think favourably; and Mr. Rennie's modification of the screw, represented in Fig. 3, is certainly very ingenious. Hunt's propeller is also ingenious, though in its present state attended with many obvious inconveniences. Capt. Carpenter's plan is a crudity, and is scarce anything more than a reproduction of one of Shorter's worst projects.

On the mode of communicating motion from the engine to the screw, Mr. Galloway makes some very judicious observations. The instruments for modifying motion are toothed wheels, straps or ropes, and friction surfaces; and as the screw has to move at a much greater velocity than the engine, the adoption of one or other of these agents is indispensable. Toothed wheels are very noisy, occasion considerable loss of power from friction, and are very susceptible of injury; friction straps are liable to stretch and slip, especially when subjected to the influences of heat, salt water, and steam; and friction surfaces

Fig. 1.

Fig. 2.

Fig. 4.

require a degree of pressure to attain the requisite adhesion, which invariably superinduces a most injurious friction in the bearings. With the view of obviating this defect of the plan of communicating motion by friction surfaces, Mr. Galloway submits the following contrivance of his own:—

"In this arrangement, shown at Fig. 4, it is proposed to use two engines of the form of which stationary engines are usually constructed, that is to say, they would have their beams above the cylinders and cranks: *dd* are the cranks, which are at a right angle to each other; *cc* the intermediate shaft; *ba* is a double coned wheel connected by the cylindric part *a*. This is all cast in one piece, and accurately turned on the conical parts *bb*; *eg* and *fh* are two wheels attached to axes *i* and *j*. They are conical at the parts *f* and *e*, and cylindrical at the parts *g* and *h*. The diameters are one-fourth of the large cones *bb*. The axis *i* is the screw axis, and *j* the adjusting axis; *k* is a spring which, by means of screws, can be made to force the cone *f* towards the axis *cc*. If, therefore, we suppose a given force to be thus communicated, it will advance the surfaces of the cones together with four times the pressure there is exerted at *k*. In this condition of the parts, if the engines be put in motion they will cause the cones *bb* to turn the smaller wheels *eg, fh*, in opposite directions; but the pressure necessary to produce contact will be principally exerted between the cylinders *g* and *h*, which, being a rolling motion, is free from friction, and the power of the engine will thus be transmitted to the screw with only a loss of power entailed by the small amount of friction at *k*. It is obvious also in this contrivance that there is scarcely any friction at the bearings of *i* and *j*, which, owing to the cones having the force communicated at two opposite points in their periphery, exert no pressure on their bearings, except that of gravity."

Fig. 3.

We question whether this expedient, though a very good one, is the one wanted. A rotatory engine appears to be the desideratum, in those cases in which the screw requires to be driven at a great speed; and in other cases it is the best plan, we think, to employ engines of a short stroke, and couple them immediately to the shaft from which the screw derives its motion. This has been done in Mr. Wimshurst's vessel with very good effect, and, we believe, will invariably be found the best mode where the screw is employed merely as an auxiliary, or occasional impelling power. We find by a note, that Mr. Wimshurst's vessel, in which this plan is adopted, had not been constructed until after Mr. Galloway's book was written; to which circumstance we must attribute the omission of all notification respecting her. We therefore feel it right to say, as Mr. Galloway would, we have no doubt, have said, had the opportunity been afforded him, that Mr. Wimshurst's plan of driving the screw is the least exceptionable of any we have met with.

London as it is. By THOMAS SHOTTER BOYS. Folio. 1842.

Mr. Boys' "London as it is" is by no means London as it ought to be, or ought to be shown. It has, in truth, altogether disappointed us, for in no one respect is it at all satisfactory, the subjects being, with merely one or two exceptions, very badly selected, either quite stale, or otherwise of little interest, and very poorly represented, at least as views of buildings, for the architecture is very slovenly, loosely, and incorrectly drawn, and treated as altogether of subordinate interest in comparison with the figures. As far as buildings are concerned, quite as good or even better representations, and those, too, far less stale in point of subject, are to be met with in some of the penny and two-penny periodicals. There are, no doubt, many who will prefer Mr. Boys' bustling London street-scenes, with crowds of vehicles of every description, to far abler executed architectural subjects; but we question whether any of that class of persons are the purchasers of four-guinea books, unless they be those whom Sir Robert Peel terms the "vulgar rich."

The title of "London as it is" would naturally lead us to suppose that the work is intended to exhibit more especially the recent architecture and improved parts of the metropolis, by way of contrast to London as it was about thirty years ago. Yet if such was its author's purpose, he has adopted a most singular mode of following out such plan, there being comparatively few subjects which might not have been shown sixty years ago. Such buildings as Temple Bar, St. James's Palace, and the Tower—or rather its mere outside walls—have little to recommend them for selection; and the views are so limited as to number, that they ought to have been carefully chosen; nor do they possess novelty of any kind, having been represented before, over and over again, and in many instances very much better. Nay, as if it was so exceedingly interesting and beautiful a subject that it could not be too much studied, Mr. Boys has given *two* different views of Temple Bar; while of Newgate—which has so much of

character and picturesque expression to recommend it to an architectural pencil—he shows nothing; of the Bank and its neighbourhood just as much; and of New London Bridge, and the new street and buildings just by it, ditto, not to mention other dittos—for that would be to make a list of almost everything worth showing. It is true, he does favour us with a sight of St. Paul's, but then it is only of a mere bit of it, as seen from Ludgate, where nearly all but the dome is concealed, and that is so drawn as to be so *unsightly*, that it might as well have been kept out of sight altogether. There is very little, indeed, to show what London is at the present day, where its street architecture has been improved. There is a view of Pall Mall, and two others of Regent Street, one of them taken from Hanover Chapel, of which not the front, but merely a single column of its portico is introduced, and that drawn monstrously out of proportion,—and they are almost all. Whatever may be his ability in other respects, Mr. Boys is evidently not a very able architectural draughtsman. In fact, he seems to have considered the buildings themselves as of very secondary importance—as nothing more than backgrounds to his groups of figures; and he would, therefore, have done better to have undertaken a work that did not require proficiency in architectural drawing, and whose title would not have held out the promise which, far as it is from fulfilling it, it now does. Foreigners, and others who have not visited London, must form not the most favourable idea of it from the representations here given of it.

The work is eminently calculated to dissatisfy and disappoint, if only by its challenging comparison with such works as Nash's "Mansions," Haghe's "Belgium," Müller's "Age of Francis I." &c., which it rivals in *price*, in size, and external appearance, but although intended so, is certainly not worthy of being placed on the same shelf with them. A similar remark applies to Morison's "Views of Haddon Hall," for though that also is *liberied* exactly like the publications we have just mentioned, it is so obviously inferior to them in execution that, even if admitted to the same table, it must be content to sit "below the salt." In truth, it is very ill-timed; had it appeared some half-dozen years ago, it might have been considered a very fair specimen of its kind, whereas now, coming after Nash's and other masterly specimens of architectural drawing and lithography, it manifests a very sad falling off. We are aware that the character we have here given, both of Mr. Boys' and of Mr. Morison's work, differs greatly from that expressed by other journals, who have spoken of both in terms of highest commendation—as they would probably do of anything else, no matter what—were it to come before them in the same imposing form and array. In fact, there are some journals which seem to keep *blank forms* of criticism, requiring merely to be filled up with the names of the publications sent to them, for the same tone, the same off-hand remarks, the same complimentary epithets occur again and again, and perhaps suit one work just as well as another.

On increasing the evaporative power of boilers, with incidental remarks on the management of furnaces and the prevention of smoke. By CHARLES WYKE WILLIAMS, Esq.

Whatever we may think of Mr. Williams' talents, we must at least allow that his industry is most exemplary. To an ordinary man the duties of managing director of a steam company would alone have afforded abundant occupation; but so lightly do those duties sit upon Mr. Williams that he is able to reconcile them with the functions of an itinerant lecturer, and maintains as great an agitation respecting his patent projects as if no other subject had a claim upon his serious attention. We might applaud this diligence if exercised in a proper spirit or expended on a legitimate object; but when devoted to the multiplication of vain and arrogant elucidations of useless and puerile devices, its only effect is to quicken contempt and provocation into active resentment. But our anger if raised is immediately softened into commiseration by the spectacle of a man so possessed with the passion for popularity, even among withered hopes and in declining years, as to hold no means unsanctified that will place in his trembling hand the glittering gaud:—querulous and irritable from the conjunction of meagre abilities with measureless ambition—and growing old in dipping buckets into an empty cistern in the visionary idea that he draws something up.

We entered so fully into the merits of Mr. Williams' projects in some of our former numbers that it would be superfluous now to re-examine them, especially as there is nothing in the present treatise capable of weakening in the least degree the force of our former arguments. We showed, we believe, to the satisfaction of our readers that the spike boiler was neither original nor efficacious, and that the argand furnace was neither more nor less than one of the old smoke

burning projects raised from the dead, and disguised under a new name, and a few insignificant variations. The proofs of these facts it is needless to multiply, and would be useless to repeat; and we mean on the present occasion to limit our remarks to the characteristics of this gentleman as an author—his merits as an inventor being sufficiently notorious.

Mr. Williams commences by giving us an explanation of the circumstances which led him to inquire into the defects of boilers, and which he says "will be a sufficient answer to the assertion that engineers and boilermakers know their business much too well to lack instruction from a pack of effervescent chemists and druggists." These circumstances are, that in 1823 he established a steam company "and undertook to have the first steam vessel constructed capable of maintaining a commercial intercourse across the Irish channel during the winter months, and which till then had been considered impracticable,"—that with respect to the perfection to which the *hulls* of steam vessels have been brought, he begs to refer to the specifications of those belonging to the City of Dublin Company furnished to the commissioners of steam vessels inquiry—and that with respect to the perfection to which both *hulls* and *machinery* have been brought, he refers us to the steam ship *Oriental*. Our readers will perhaps be puzzled to discover what all this has to do with the allegation that engineers and boilermakers are at least likely to know something more of engines and boilers than a parcel of empty and self-sufficient apothecaries; and indeed we are at a loss to discern any purpose in these intimations, unless it be to impress us adequately with Mr. Williams' importance. But we think the illustrations peculiarly unfortunate: the specifications referred to are very imperfect in many respects, and all the world knows that the most of the vessels belonging to the City of Dublin Company are the worst planned and most unsightly tubs afloat. The *Oriental* is certainly a fine vessel, though we are not aware of anything peculiar about her for which particular merit can be claimed: but nothing can be clearer than if the nature of Mr. Williams' responsibility be such, that to him is due the merit of success, to him should also be due the demerit of failure if failure arise. Now the *Liverpool*, the consort of the *Oriental*, and also under Mr. Williams' controul, *was* at first a failure; yet Mr. Williams declines all participation in the blame consequent thereupon: so that it would appear to be his happy prerogative to monopolize all the credit of success, and throw the odium of failure, as often as it occurs, upon some other person. Mr. Armstrong states in his treatise on steam boilers that the return of the *Liverpool* on her first voyage to New York arose from the introduction of some species of smoke burning scheme—or at least some tampering with the furnaces of which the makers of the machinery did not approve; and although Mr. Williams denies that this was the cause of the failure, he admits that such interference actually took place with the view, he says, of *relieving*, if it could not *remove*, certain supposed defects in the construction of the boiler. This admission settles the question: for if the boilers were taken out of the hands of the manufacturers, and the furnaces altered to suit the views of other parties, the manufacturers could not be held accountable for the result: and as the same boilers, so soon as the furnaces were restored to their original mode of action, enabled the vessel to make subsequent voyages to New York without any failure, it would certainly appear that the first failure arose not from any inherent defects in the boilers themselves, but in consequence of the introduction of some *improvement* which when removed or discontinued enabled the boilers to operate with their proper efficacy.

It had always been our impression that steam communication had been maintained across the Irish channel during winter antecedently to 1823; but Mr. Williams assures us that up to that date the maintenance of a commercial steam intercourse during winter was looked upon as impracticable. Now a commercial steam intercourse could hardly be held to be impracticable if any kind of steam intercourse had previously been maintained; for the doubt was not whether a bale of muslins could be carried, but whether the voyage could be performed under adverse circumstances of wind and water; and as this doubt continued to exist according to Mr. Williams up to 1823, when he first built a steamer, and showed it to be without foundation, we must set him down, as by his own showing, the first person who accomplished regular winter voyages across the Irish channel. Now in a report of a Select Committee of the House of Commons of the date of May 2nd, 1822, and another of the date of June 12th, 1822, we find it stated that a steam communication had been maintained all the preceding winter across the Irish channel, and that numerous steam vessels commercial and others had maintained a regular winter communication upon the open sea for some time previously. We confess ourselves unable to reconcile this statement with that of Mr. Williams, that up to 1823 when he began operations such an achievement was looked upon as impracticable; and we trust that our readers before they arrive at

any conclusion, will weigh well the testimony on both sides of the question. On the one side they have the positive assertion of a gentleman of experience and station upon a matter personal to himself, and in which it is hard to suppose he could be mistaken. Upon the other side they have the declarations of a committee of the House of Commons, backed by the evidence of a host of witnesses who it cannot be supposed had any desire, even if they had the power, to falsify a matter which must have been abundantly notorious. Every reader must form a conclusion for himself from the balance of evidence before him, and will probably adopt that opinion which involves the least wonderful supposition.

The general character of the present work is identical with that of Mr. Williams' other literary productions:—intolerably prolix—marvellously superficial—and absurdly ostentatious: and indeed these are among the cardinal specialities of the minute philosophy and the natural concomitants of imbecile pretension. An author of this class never knows when to have done—he is unwilling to lose any opportunity of making the most of his talents and materials—and takes especial care that nothing of the least moment shall be dismissed till its merits have been made apparent to the most impenetrable or inattentive. In the idea that anything which has once suggested itself to him cannot be unimportant to the world in general he gives his readers—not a selection of his conceptions—but them all, and dilates and elaborates the most paltry truism to the consequence of an important proposition. He does not possess the forbearance to state his views and arguments in a popular and concise manner, and cast them upon the waters of public opinion to sink or swim as their merits determine; but must have long speculative introductions and learned mystifications—endless repetitions and digressions—illustrations and deductions—recapitulations of what every body knows, and demonstrations of things nobody ever thinks of doubting—objections anticipated and answered—and predictions as to the influence of his doctrines upon the fortunes of all men, and the destinies of all future generations; and if an idea of more than ordinary value is hit upon, it is exhibited in so many different lights and reproduced in so many different attitudes, that its whole force and elasticity are extinguished,—the reader is wearied, perplexed, disgusted,—and turns with aversion or pity from the perpetual display of such vain ambition and such conspicuous penury.

But we question whether the operose dullness of Mr. Williams' literary perpetrations constitutes their most exceptionable characteristic. There is a vein of disingenuousness running through them which often excites our shame and provocation, and their uniform tone of arrogance and pomposity cannot fail we fear to alienate every reader's affections, and give rise to associations not by any means favourable, and nearly, if not altogether indissoluble. Indeed this gentleman's arrogant and emphatic manner operating upon his habitual trick of overrating all his own conceptions, occasionally gives rise to the most ludicrous combinations. His revelations are preceded by such a note of preparation, and such precautions to ensure for them a distinguished reception, that the highest expectations are excited, and when after having prepared his hearers for something very impressive, he utters, as is often the case, only an *italicised* truism or inconceivable stupidity, the ridicule is irresistible, and its effect scarcely ever to be got over. Such a failure admits neither of toleration nor apology—it makes weakness manifest where a display of strength was intended—and must eventually be fatal to the faith of the most credulous even of his disciples.

We regret to find, that Mr. Williams has in the present work repeated the absurd charges he brought against our mechanical engineers on a former occasion, of being altogether ignorant of the chemistry of combustion, and of knowing nothing whatever about boilers. Our engineers have treated these charges with the significant silence to which, perhaps, they are alone entitled; but our function leaves us no such option, and we feel called upon to tell Mr. Williams articulately and in direct terms, that his charges are unfounded. If our leading engineers know nothing about engines or boilers, where is such knowledge to be found? Does Mr. Williams imagine that he or the most accomplished master of gasconade or falsetto will be set down as the depository or originator of that mechanical proficiency which has made this country the envy and admiration of surrounding nations—added dignity to her sceptre, and magic to her name? Or shall we conclude that Mr. Field, Mr. Farey, Mr. Miller, Mr. Brown, and numerous others we could mention—men who would be ornaments to any profession, and on whom the mantle of Watt has descended—have spent a life-time of laborious study and experience in achieving no progress and acquiring no knowledge, and are up to the present moment ignorant even of those elements of chemistry with which every school boy is conversant? One of two things is clear: either Mr. Williams makes a statement he does not himself believe, or sup-

poses that to be acquainted with any simple truth it is necessary to rave and fume, and vociferate respecting it. It appears never to have occurred to him that true science is a thing which shuns all display and noise, and that eminent merit is generally united with eminent modesty.

The Hand-book of Manchester. By B. LOVE. Manchester: Love and Barton.

This is a well-illustrated work. It contains a description, with views, of most of the public buildings of Manchester; likewise some interesting statistic information connected with its manufactures. It is a book that ought to be in the hands of every visitor to that important "Metropolis of Manufactures."

REPORT OF THE COMMISSIONERS ON THE FINE ARTS.

REPORT.

WE, the Commissioners appointed by your Majesty for the purpose of inquiring whether advantage might not be taken of the rebuilding of your Majesty's palace at Westminster, wherein your Majesty's Parliament is wont to assemble, for the purpose of promoting and encouraging the Fine Arts in your Majesty's United Kingdom, and in what manner an object of so much importance might be most effectually promoted, humbly report to your Majesty that we have taken into our consideration the matters referred to us, and have given due attention to the Report of the Committee of the House of Commons in 1841 on the Fine Arts, together with the opinions of various other competent persons on questions relating to the special objects for which the present Commission was appointed, and have consulted the architect as to the manner in which various kinds of internal decoration would affect his intended architectural arrangements; and we beg now to report our opinion that it would be expedient that advantage should be taken of the rebuilding of the Houses of Parliament for the purpose of promoting and encouraging the Fine Arts in the United Kingdom.

Having thus come to an opinion on the first point to which our inquiry was directed, we have, in conformity with the instructions contained in our Commission, proceeded to consider in what manner the above-mentioned purpose could best be accomplished. With this view we have, in the first place, directed our attention to the question whether it would be expedient that Fresco painting should be employed in the decoration of the New Houses of Parliament, but we have not yet been able to satisfy ourselves that the art of Fresco painting has hitherto been sufficiently cultivated in this country to justify us in at once recommending that it should be so employed. In order, however, to assist us in forming a judgment on this matter we propose that artists should be invited to enter into a competition in Cartoons, and we have prepared the draught of an announcement on this subject, offering premiums of public money, to which we request the sanction of your Majesty.

In framing this announcement we have felt that, although the competition which we at present wish to invite has reference chiefly to Fresco painting, yet if we were to confine our notice entirely to that method of painting, an inference might be drawn therefrom that we intended to recommend its exclusive adoption for the decoration of the new buildings. We have, therefore, inserted in our announcement paragraphs intended to explain that the future attention of the Commission will be directed to the best mode of selecting for employment artists skilled in oil painting and in sculpture, and that due consideration will be given to other methods and departments of Art applicable to decoration generally.

We humbly subjoin as an Appendix to this Report, some papers treating in detail various considerations connected with the subject of our inquiry.

APPENDIX.

The general object of the Commission considered in relation to the state and prospects of the English School of Painting.

As the Commission is understood to take up the present inquiry where the Committee on the fine arts, appointed by the House of Commons in 1841, left it, it will be proper, by way of introduction, to recapitulate the leading opinions expressed in the Report of that Committee.

It was there observed that "the chief object aimed at by the appointment of the Committee," was "the encouragement of the fine arts of this country;" that it was "requisite that a plan should be determined upon, and that as soon as practicable, in order that the architect and the artist or artists to be employed, may work not only in conjunction with, but in aid of each other; that thus the abilities of both would be exerted for the decoration of so eminently national a building; and at the same time encouragement beyond the means of private patronage, would be afforded not only to the higher walks, but to all branches of art." The report proceeds to recommend the employment of fresco painting in the decoration of the new Houses of Parliament, suggesting, however, the necessity of further information and inquiry.

The appointment of the Commission has fully secured the latter, and the general objects of the Committee have been recognised in the notice respecting a competition, already prepared for publication under the sanction of Her Majesty's Commissioners.

It is here proposed to consider the question of the decoration of the Houses of Parliament with reference to the state and prospects of the English school of painting. And first it is to be observed that, although "all branches of art" may be entitled to the consideration of the Commission, historical painting is not only generally fittest for decoration on a large scale, but is precisely the class of painting which, more than any other, requires "encouragement beyond the means of private patronage." The want of such encouragement has long been regretted, not by professors only, but by all who have turned their attention to the state of painting in England;—a proof that the promotion of historic art is an object of interest with a considerable portion of the public.

The inference is not unimportant; for an already existing estimation of the higher aims of art, is in itself an earnest of their success. The desire which has been manifested for historical painting would not be entitled to attention if it could be traced to a passing influence, or to a disposition to imitate what had been achieved in other countries, since this could only lead to the adoption of superficial qualities, betraying, sooner or later, the absence of a vital impulse. Such attempts would be the more likely to be ineffectual, if a different style, however humble, really corresponding with the national taste, were at the same time cultivated with marked success. The history of art is not wanting in examples of schools and of periods, with regard to which it might be a question whether a sudden demand for historical painting would have been a boon to the artists or to the lovers of art. The Dutch school of the seventeenth century might be adduced as a case in point.

It may here be remarked that, even where the direction of national taste is favourable to the cultivation of historical painting, the peculiar difficulties of that branch of art must sometimes place it in unfavourable contrast with inferior departments more commonly practised, and in which a relative perfection is more commonly attained. The disadvantages resulting from this contrast are peculiar to modern times: at the revival of art and during its progress to excellence the efforts in the grander style were not in danger of being undervalued, or stimulated to injudicious rivalry, by such a comparison. No school exclusively devoted to indiscriminate imitation then existed. The present influence of such schools and examples may partly account for and excuse the occasional fastidiousness of modern amateurs with regard to efforts in historical painting, and may render a consistency of style more difficult for the historical artist.

These admissions with regard to the present difficulties of the highest style of art cannot, however, render it necessary to vindicate its abstract claims; the sole question for consideration now is, whether in this country and at this time there exist grounds for hoping that historical painting could be cultivated with success, and whether it would awaken a more general interest, if it were duly encouraged by the State.

That the actual estimation of this department of art has direct reference to the moral wants of our own nation, is further proved by the repeated exertions of individuals in proposing plans for the promotion of the higher style of art, by the generous encouragement occasionally extended to its votaries by others, but above all by the efforts of the artists themselves. For it must always be borne in mind that the aims of the artists are not to be considered as accidental predilections apart from the public feeling, but as representing a portion of that feeling. However variously modified by other influences, the formative arts must always express the manners, the general taste, and, to a certain extent, the intellectual habits of the nation in which they are cultivated; the chief conditions with regard to the last being, that the objects of mental interest should be analogous to the pursuits of taste, and at the same time familiar to that portion of the public to which the arts are addressed.

But to whatever extent the mind or manners of a nation may be communicable to its productions in art, the result is to be looked for rather in general tendencies than in degrees of technical excellence, and is especially to be sought where controlling influences, even of a salutary kind, are least likely to interfere with the free expression of national taste. Thus, the indications in question are not so evident in religious subjects, in which a common education, and long consecrated themes, have tended to elevate to a common standard the taste of the civilized world; nor are they so distinctly manifested even in certain subjects of local interest, such as the acts of illustrious individuals, and the commemoration of national events; themes which patriotism has everywhere supplied, and which presuppose a uniformly ennobling influence. The proper and peculiar tendency, the physiognomy, so to speak, of national taste, is to be detected in more spontaneous aims; in the direction which the arts have taken, when their course has been unrestrained, save by the ordinary influence of the intellectual and moral habits of society.

It might be interesting to trace the connexion between the arts and national culture and character under such conditions; but the general truth of the view above taken has been so often dwelt on by the historians of art, that it must be unnecessary to adduce examples of such a connexion where circumstances must render it more than commonly direct. If it were proposed to compare the English school of painting (as regards its general tendency) with the schools of other countries, it would, however, be just to consider the direction of taste in the latter when art has not been employed in the service of religion and patriotism, for it is under these circumstances that painting has been cultivated in England. The result of such a comparison would tend to vindicate the aim and character of the English school.

But the inference from the above statement, which is more immediately applicable to the present question, is, that the efforts of the English artists in the higher branches of their profession are to be regarded as an evidence of the tendency of taste in a considerable portion of the public, and it remains to observe that both the efforts and the taste may be almost irrespective of the common relation between demand and supply, since the due encouragement of the higher branches of art may be "beyond the means of private patronage." This apparent contradiction of a moral demand, for a particular class of art, existing independently, in a great measure, of its usual consequences—the actual employment of those who, with due encouragement, might respond to it, is explained by the fact that the decoration of public buildings, with a view to moral or religious purposes, has always been necessary for the formation of a school of historical painting. The history of arts shows that whatever may be the extent of general education, the service of religion or the protection of the state is indispensable, at the outset at least, for the full practical development of the highest style of painting. Thus formed and thus exercised historic art lives and is progressive, but with the aid, however liberal, of private patronage alone, either its aim becomes lowered, or its worthier efforts are not sufficiently numerous to re-act on the general taste.

To many it may appear unnecessary to assert the capacity of the painters or of the public for the cultivation or appreciation of elevated art. But it must be remembered that while the great stimulus and support of public employment is wanting, the exertions of the artists are gradually compelled into other directions; and some observers, looking at this result alone, may draw erroneous inferences from it,—may sometimes hastily conclude that pictures of familiar subjects, which have been of late years predominant and deservedly attractive, represent the universal and unalterable taste of the nation.

Such observers might, however, at the same time remark that the productions in question oftener approach the dignity of history than the vulgarity of the lowest order of subjects, and either by the choice of incidents, or by their treatment, still attest the character of the national taste. The evidence of an intellectual aim in familiar sub-

jects, may be therefore considered as an additional proof that the artists of England want only the opportunities which those of other nations have enjoyed, in order to distinguish themselves in the worthiest undertakings. But to place this question in its proper light, it will be necessary to take into consideration the peculiar circumstances under which the English school has been formed.

The great impediments to the cultivation of the higher branches of art have been already adverted to. With few exceptions, painting in England has not been admitted into churches, (a subject which it is not intended here to discuss) nor has it been employed to any extent in the embellishment of public buildings. Other difficulties have existed, owing to various accidental circumstances.

The perfection which the great Italian masters arrived at, was the result, it is true, of slow experience, but happily for them the more ornamental and fascinating qualities of the art were attained last. With the English school it was the reverse. Its rise in the last century was remarkable for sudden excellence in colouring and chiaroscuro, an excellence so great, as to eclipse contemporary efforts in a severer style, while it gave a bias to the school. The peculiar union of what are called the ornamental parts of the art, with those essential to history, which has prevailed in England, not unattended with some sacrifice of more solid qualities, has been generally attributed to this influence.

This mixed character became more decided in consequence of the circumstances under which the school was developed; namely, the subsequent introduction and prevalence of a style suited to small dimensions. Most of the distinguished English artists in the time of Reynolds painted the size of life. The experiment, as regards private patronage, seems to have been then fairly made, and the gradual change to reduced dimensions, appears to have been the consequence of the insufficient demand for large works, arising in a great degree from the limited size of English dwelling-houses.

Hence the execution of small historical pictures; a practice recommended by the occasional example of the best masters of every school. But where the subject is dignified, smallness of dimensions cannot consistently be accompanied by smallness of treatment. Minute imitation is not found in Correggio's Gethsemane, nor in Raphael's Vision of Ezekiel, diminutive as they are. The breadth of manner which is indispensable in such elevated themes is not, however, essential in familiar subjects, and hence, when specimens of both styles, similar in size, but widely different in their technical conditions, are placed together, the impression produced by so marked a contrast is unsatisfactory, without reference to the difference of subject.

Thus, partly through the influence of the "ornamental" character of the school, and partly to prevent this abrupt contrast of treatment in pictures which are to hang together in galleries, (for under such circumstances, the more abstract style appears to disadvantage,) the kind of historic art chiefly followed, is that which admits picturesque materials, thus combining the attractions of familiar subjects, with the dignity of the historic style. Under such influences has been formed an interesting portion of the more modern English school, distinguished on the one hand from the Dutch, and on the other, from the small works of the Italian masters, embracing a great variety of subjects, sometimes scarcely removed from the familiar, sometimes approaching the grandest aim.

The circumstances that have led to the general adoption of a small size are thus it appears, accidental, and the actual practice of our painters cannot be adduced as a proof of their original choice of such conditions. The frequent efforts on their part, amid various difficulties, to recommend larger dimensions, are a sufficient proof of the real inclination of the artists. These efforts have not been confined to the ardour of youthful inexperience; many of our best artists have returned to, or persevered in such undertakings to the last; with some, the ambition to encounter the difficulties of this style was first kindled at an advanced period of their career. In the last century all the principal English artists, notwithstanding Hogarth's success in small pictures, were in the habit, as already observed, of painting the size of life—Reynolds (considered as an historical painter), West, Barry, Fuseli, Copley, Northcote, Opie, and others.

It cannot therefore be admitted that the artists of England are, by their own choice, confined to small dimensions; but the questions now are—

Whether it is possible to afford more favourable opportunities than those which have hitherto existed for the adequate display of historic art?

Whether such opportunities will be sufficiently numerous? for if not, the school, after attaining the excellence which honourable employment will assuredly call forth, may again languish; and, lastly,

Whether such encouragement will be in danger of diverting the

taste and practice of some artists from that domestic art which is now so successfully cultivated?

The first of these questions, while it is immediately connected with the special object of the Commission, involves the consideration of the abstract relation of dimensions to styles of art. This subject has been often discussed on grounds independent of technical requisites, and as very different opinions have been the result, it may here be allowable, without undervaluing the conclusions derived from other considerations, to refer to the mere physical or external conditions which must necessarily affect the question.

In comparing the treatment of cabinet pictures with that of works of the largest size—for example, where the figures are colossal—it may be observed that the small picture, besides being executed with delicacy, generally exhibits a certain fullness of detail, while the large work is not only less elaborate, but is composed of fewer parts. Even assuming the same subject, and one requiring a variety of minute accessories, to be represented on a colossal and on a small scale, it may be safely affirmed that the degree of detail which would be admissible in the small picture would be objectionable in the larger. In a grander and more ideal subject, where such detail would be inadmissible under any circumstances, the comparison could be less fairly made, but a similar influence would be more or less apparent. Thus, assuming other conditions to be common, the greater space never allows the introduction of *more* detail than the smaller, but generally, if not always, requires *less*.

Without entering into the examination of this question as connected with the laws of vision, it may be remarked that although the indistinctness arising from distance may be counteracted, as regards the most important qualities in art, by increased dimensions, and by appropriate style and treatment, it must still tend to exclude certain refinements of imitation which are appreciable in pictures requiring to be seen near—refinements capable of conferring an interest on details that may be unimportant in themselves. The inference is at once applicable to the question proposed. The familiar subject, as fullest of accidental circumstance, must be best displayed in dimensions fitted for near inspection, and, in an advanced state of art as regards imitative excellence, must be a consequence of the habitual adoption of such dimensions. On the other hand, the larger the figures in a picture, the greater the distance at which the work must be seen; and as the omission of detail is a consequence of that reduced scale of gradation which distance supposes—as the absence of minute particulars is felt to be the attribute of distance without reference to the size of objects, so the accessories in the larger work of art require to be few and important. Thus, again, increased dimensions, by involving the suppression of detail, suggest subjects of corresponding dignity.

Such appears to be the relation of dimensions to style and subject, considered with reference to technical results; as regards the question of taste, it may be observed that the involuntary conclusions derived from the influence of association agree with the practice of art. The analogy between grandeur and the absence of detail, and between minute circumstance and familiar incidents, is sufficiently apparent. With these analogies, the impressions produced by magnitude and its attributes, and by the opposite qualities, respectively correspond.

The general relation thus defined has often been reversed in works of art, but not with equally good results, for it may be remarked that large works, when elaborate in detail, and full of accidental circumstance, have the unpleasant effect of magnified cabinet pictures; on the other hand, diminutive historical works, when treated with that breadth which belongs to the grandest style, must give the impression of large works diminished. The last-mentioned inconsistency can hardly be objected to; grandeur of conception and treatment must unquestionably be acceptable in any form, but nevertheless the abstract breadth of imitation which is indispensable in elevated subjects is, under the circumstances supposed, a kind of contradiction, inasmuch as the vague generalization of a distant or ideal effect is submitted to close inspection, and can only be so viewed. The small pictures by Raphael and Coreggio, before referred to, are of this description; but the instances of such subjects being treated on so minute a scale are not frequent.

It is unnecessary to enumerate other exceptions, or to refer to larger works in which a just adaptation of style may have tended to obviate an incongruity between subject and dimensions. It may be sufficient to have dwelt on those plainer principles which result from the technical and external conditions that have been considered, but which may afford a criterion with regard to some of the more arbitrary conventions of works of art.

It may be added that even the extreme conclusions which might be deduced from the conditions referred to, are strictly conformable to the authority of the grandest examples of art. The loftier aim of imitation thus defined, may seldom be literally compatible with the

usual range of subjects; but in this instance, again, the criterion, as such, may be admissible. Thus, assuming the representation to be dilated to its full measure, details of costume, illusion, and even the more delicate varieties of colour are no longer fitted for the dimensions. But in proportion as the subordinate excellences of imitation are excluded by the nature of the existing technical conditions, the display of the nobler qualities still attainable becomes more necessary. As the resources of art become more circumscribed, the artist's aim becomes elevated. In the highest style of painting, as in sculpture, the representation of inanimate substances ceases to be satisfactory when they no longer directly assist impressions of beauty or grandeur: and the styles of art in which the living form can be least dispensed with, are precisely those which, by the abstract character of their imitation, render it least objectionable.

The foregoing considerations may warrant the conclusion that the grandest style of art is best displayed in large dimensions. It will also follow that the treatment of subjects fitted for such dimensions, must tend to ennoble the style and taste of the artist.

Works of such magnitude, cannot be often in demand for ordinary dwelling-houses: hence, while pictures are excluded from churches, the places in which it is possible and desirable to employ the higher branches of art will be the national and municipal public buildings; all localities, in a word, where painting can be displayed to the public in its highest and most didactic form.

But will such opportunities and means of encouragement be sufficiently numerous and enduring? The answer to this important question can be best anticipated by the exertions of the artists; it may be reasonably expected that the employment of native talent in a great national building, will serve as an example throughout the country, and that the style of art which will be thus recommended and promoted, may be even adopted in fit situations for the decoration of the mansions and villas of affluent individuals.

In answer to the third question proposed, namely, whether the encouragement of historical painting, may tend to alter the direction of the taste and practice of those artists pursuing a hitherto more thriving and popular branch of art? it may be allowable to observe that even such a danger would be no just argument against the employment of deserving candidates for fame in another department. But the long neglected interests of the historical painters, can, it is believed, be promoted without interfering in any degree with the prosperity of the class in question. That school is already formed; and the cause to which it chiefly owed its rise,—the possibility of its productions being placed in apartments of ordinary dimensions, must ensure its duration; added to which, the societies for the encouragement of art by subscription and lottery, have solely in view the acquisition and distribution of comparatively small pictures. The object now is to find opportunities as fit, (they cannot possibly be as numerous,) for the development and display of historical painting on a large scale. Whatever may be the influence of the proposed encouragement on the rising generation of artists, it is at all events desirable that inclination should be free; that the inheritors of that enthusiasm which prompted the best English artists of the last century, to offer to decorate St. Paul's Cathedral and other buildings at their own expense, may no longer ask in vain even for space.

The general tendency of the national talent, has been hitherto considered in a great measure apart from the question of the actual qualification of the artists. It may be sufficient, in reference to this part of the subject, to acknowledge that the difficulties of the style of art which is now proposed, may be peculiarly great in England, owing to the circumstances before adverted to, and that no common energy may be necessary to surmount such difficulties. But while the artists are expected to show themselves worthy of entering on that career which is now opening to them, it is but just to remind the enlightened judges of art who refer to the great works of other countries, that those works were the result of repeated essays, and that considerable time was necessary for the formation of the taste and practice of those who produced them. In justice to the artists, the trial should be as fairly made in England.

On ordinary occasions the imitative arts may be considered as adventitious embellishments, but in proposing to adorn an important national edifice where it is essential that a characteristic unity of design should be maintained throughout, painting should appear as the auxiliary of architecture. It was thus that it was employed in the best ages of Greece and Italy, and it was thus that its highest development was ensured. In the present instance the chief decorations in painting will be required to be on an extensive scale. The difficulty of keeping large masses of canvas well stretched during all changes of weather, has been considered an objection to the employment of that material under such circumstances. The evil here alluded to may be seen in its worst form, in the ceiling of the chapel at Whitehall, owing

to the surface of the paintings being highly varnished. The fittest kinds of painting, for the decoration of architecture, are those which can be applied, when required, to every surface, curved as well as plain, and for such general decoration, fresco—recommended as it is by the example of the great masters—appears to be better adapted than any other method.

The objections to the employment of fresco in London, on account of the smoke, have not been overlooked, and various information respecting the mode of cleaning such paintings has been collected. The opinions of Director Cornelius on the subject will be found in his statements. Professor Hess, on being consulted on this point,* remarked that "if frescos were painted in the open air in London, the rain would be the best picture cleaner." The observation is so far important, that it assumes the possibility of washing frescos freely without injury to the colours. Mr. Thomas Barker, of Bath, who painted a fresco of considerable extent in that city some years since, writes;†—"To clean fresco from smoke, I know of no mode so simple and efficacious as washing the surface with pure water, using a soft sponge in the operation." Mr. Barker elsewhere observes:—"It is now seventeen years since the completion of that work;" (the fresco he painted)—"if any change has taken place, it is in the colouring having become much more effective than when first completed." Mr. Andrew Wilson writes from Genoa‡ that frescos there are cleaned with vinegar, so as to look as fresh as when first painted. Carlo Maratti used wine in washing the Vatican frescos, and succeeded in restoring the principal paintings notwithstanding the injuries and neglect of nearly two centuries.§ There seems, therefore, to be no reasonable ground of apprehension on this account. With regard to the effect of the English climate, no very accurate conclusions can be arrived at, as the examples of older frescos in this country are not numerous. About the middle of the last century some frescos were executed at West Wycombe Park, by Guiseppe Borgnis, a Milanese, under the auspices of Francis Lord Le Despenser. The paintings are exposed to the open air, yet those in the east portico and south colonnade and loggia, are in general remarkably well preserved. The paintings in the west portico, from whatever cause, have suffered considerably. The east portico is an agreeable example of the union of fresco-painting with architecture; in the soffit is a copy of Guido's Aurora. Some ceilings in the interior appear to be painted in oil.

As long as any doubt is expressed as to the mode in which the antique paintings which have been preserved were executed,|| it may not be allowed to quote those works as examples of the durability of fresco painting in particular; but they afford strong evidence of the durability of painting on well prepared walls. Sufficient examples, however, of frescos, properly so called, that have stood for many centuries, exist in Italy. Among them may be mentioned: at Padua the works of Avanzo, though injured in lately removing the whitewash with which they were covered; in Florence those of Benozzo Gozzoli in the Palazzo Ricardi, of Angelico da Fiesole, Masaccio, and others; in Perugia those of Perugino; in Assisi those of Giotto, (the vows of St. Francis);¶ these works belong to the 14th and 15th centuries. In S. Giacomo, Spello, Orvieto, Pisa, Siena, and Rome, various examples by the earlier masters are in good preservation, when unhurt by violence. The works of Luini, at Saronno and Lugano, may be mentioned as remarkable instances of frescos in perfect preservation after three centuries.** It has been supposed that the sea air at Venice may have affected the few frescos painted in that city; but in Genoa, where the influence of the sea air is more immediate, and the effect of storms more severely felt, frescos have lasted on the external walls of houses for some centuries.††

The practice of fresco painting, as far as description can explain it, is sufficiently detailed in the papers of the Appendix which follow, but it may be desirable briefly to examine its general qualities as a means of representation.

Its difficulties are not to be dissembled; they are, however, not the difficulties of the mere method, but arise from the necessity of an especial attention to those qualities which rank highest in art; qual-

§ Memoir in the second edition of Bellori's Life of C. Maratti.

|| According to Sir Humphrey Davy's experiments, the antique painting called the Aldobrandini Marriage was unquestionably executed in fresco; no colours were found in it but such as stand in fresco, and the white pigment was lime. Other paintings appear, from his description of the materials, to have been executed in tempera, though he calls them fresco; but no wax (used in the encaustic method) was found in any of the specimens examined by this great chemist in Rome. (See The Philosophical Transactions, 1815, p. 97). In Pompeii specimens of encaustic are said to be frequent.

ities which, when not absolutely indispensable, are too often neglected. Defects in composition, form, action, expression, and the treatment of drapery may be redeemed in an oil painting by various merits; not so in a fresco. A style of art thus circumscribed cannot, therefore, be recommended for exclusive adoption; but if studied together with oil painting, its influence can hardly fail to be beneficial. The great Italian masters, as is well known, practised both methods; hence their employment, frequent as it was, in fresco, led to no imperfection, but on the contrary, may be considered to have been mainly conducive to the vigorous character of Italian design.

The immediate and necessary connexion of this mode of painting with the highest aims of art, fits it to embody those inventions which belong essentially to the domain of thought. As a mode of decoration for public buildings it has peculiar recommendations: no style of painting is more clear, distinct, and effective at a distance. This is partly to be referred to the thorough execution, founded on the intelligence of form, which it requires, and to the brilliancy of the material employed for the lights. But there are other causes of this distinctness of effect more directly connected with general design. With dimensions and distance, and a treatment that depends rather on power of light than on intensity or quantity of shade for its effect, a style arises which develops the elements of composition in some measure distinct from *chiaro-scuro*. The influence of these conditions is apparent in the best Italian frescos, which, at the same time that they exhibit the happiest adaptation of perspective and foreshortening, and often the most skilful management of gradations of light, are remarkable for impressive clearness of arrangement.

This style of composition is still more apparent in the celebrated cartoons of Raphael, in which it is carried to the most emphatic simplicity, still combining the picturesque principle of depth, as opposed to the flatness of *basso-relievo*. These works were evidently treated with reference to the material in which they were to be ultimately executed, namely, tapestry; in that material, as wrought in Raphael's time, powerful effects of light and shade were unattainable—a defect attempted to be remedied by heightening the relief of some of the objects with gold. The figures are, however, colossal in size, as the works were to be seen at a considerable distance, and the great artist attained distinctness by means of composition almost alone. The principal figures are rendered important chiefly by the place they occupy, and the story is comprehended at the first glance; thus a skilful arrangement supplies the absence of those modes of relief which might be resorted to in oil-painting; indeed the effect of light and shade, making every allowance for the injuries of time, is far weaker than that attainable in fresco.

But assuming this general style of composition to be applicable to fresco, it cannot be objected that, owing to its peculiar fitness in the case referred to, it would in any degree disqualify the artist for the practice of composition in oil-painting; for the cartoons of Raphael have always been considered to be among the most perfect examples of arrangement and of masterly clearness in telling a story, without any reference to the particular conditions which may have influenced the painter.

In like manner as regards colouring, the practice of fresco has never been found to have any unfavourable influence on that of oil painting, but rather the reverse. Without referring to particular works as instances of the perfection in both methods which the Italian masters of different schools—*Francia* and *Raphael*, *Andrea del Sarto* and *Guido*, *Gaercino* and *Pordenone** attained, it may be sufficient to mention the example of *Corregio*—in the opinion of *Reynolds*† the most consummate of painters as regards colour and execution. This great artist painted more in fresco than in oil, looking to the quantity of surface covered. In his case it is evident that even the comparative absence of depth and mass of shade in fresco had no unfavourable influence on his practice as an oil painter; while the clearness of his colouring in his oil paintings may not unreasonably be attributed in some degree to his experience in the other method.‡ And here it may be allowable to express the opinion, that the great skill of the

English artists in water colours might be the means of introducing new technical merits and a new perfection in the practice of colouring in fresco, which might again directly benefit the school of oil painters.

The foregoing are among the considerations which, it is considered, might induce her Majesty's Commissioners to recommend the promotion and encouragement of historical painting in connection with the rebuilding of the Houses of Parliament, while a hope may be here expressed that the example will be followed on other occasions. The employment of fresco, for a portion at least of the intended works might be proposed conditionally, since it must necessarily depend on the evidence of inclination and qualification on the part of the artists, to work in that method.

C. L. EASTLAKE, *Secretary*.

STATEMENTS OF DIRECTOR PETER VON CORNELIUS,

Relating to the Proposed Decoration of the Houses of Parliament.

The following statements contain the substance of some opinions expressed by Director Cornelius on the proposed decoration of the Houses of Parliament. The particulars relating to the practice of fresco painting are extreme only from more copious details freely communicated by him. For some few allusions to facts in the history of the arts, connected with the subjects discussed, the Secretary of the Commission is responsible. These additions are distinguished by brackets, or are given as notes.

The Situation.—Cornelius, the distinguished artist who has executed so many works in fresco at Munich and elsewhere, inspected the plans for the new Houses of Parliament, as well as the site of the buildings, during his short stay in London in November, 1841. His attention was first directed to the general situation, with reference to works in fresco. He thinks the situation unobjectionable. He has no idea that the damp of the river can have any effect on fresco paintings in rooms elevated as those in question will be above the actual level of the water. The effects of damp in the atmosphere are not apprehended by the German painters. Many failures that might have been hastily attributed to damp, were really owing, Cornelius observes, to the use of lime in too fresh a state. Of the experimental works painted at Munich in the open air those only have faded which are known to have been done without due attention to the materials. Thus, a figure of *Bavaria* painted by *Kaulbach*, which has faded considerably, is known to have been executed with lime that was fresh. Similar failures in less exposed situations have been traced to the same cause. The cupola of *Val de Grace* at Paris, painted in the 17th century by *Mignard*, faded soon after it was done, though sufficiently elevated above damp exhalations, because the lime used was too new.

The damp which, in the opinion of Cornelius, is really prejudicial to fresco, is that which is occasioned by the use of unseasoned materials—new timber, imperfectly burnt bricks, &c. The nitre which is so destructive to fresco he supposes to originate from the stones of the wall rather than from the mortar. Such causes of decay might exist in high and dry situations from want of care. But Cornelius lays the greatest stress on the necessity of using lime that has been long kept, since this comes in immediate contact with the colours, and is a colour itself.* When this eminent artist, in conjunction with others, painted the house of the *Chevalier Bartholdy*, in Rome, an old man who had been employed under *Mengs* (a not unskilful fresco painter,) directed their attention to this point, and it so happened that they were then supplied with lime which had been preserved twelve years. The works alluded to, though the first executed by the modern German fresco painters, have stood perfectly well.

Among other precautions it is desirable to let the building itself dry well before painting the walls: yet Cornelius painted in the *Glyptothek* at Munich, not long after it was finished, from a confidence in the soundness and dryness of the materials. He however took the precaution to use water that had been boiled in moistening the surface and in thinning the lime.

The Style of the Architecture.—With respect to the question whether it is possible to preserve a due congruity between the modern taste in painting and Gothic architecture, the opinion of Cornelius is unhesitating; but this opinion, it will appear, is the result of particular views respecting the standard of pictorial excellence. He thinks the Italian works which the Germans most approve, and modern German art itself perfectly fit for such a purpose. The works of *Heinrich Hess* in the *Allerheiligen Kapelle* at Munich are, he observes, in one sense, a case in point, since that chapel is in the Byzantine style of architecture, the date of which is still earlier than the so-called Gothic. In these frescos the space round the figures is often gilt, and thus the rude splendour of a remote period is united with a grandeur of design derived from the purest examples of Italian art.

It is well known that in the middle ages the cathedrals and churches throughout Europe, however varying in their style of architecture, were more or less decorated with painted and gilded ornaments and scriptural or legendary subjects. [Vestiges of paintings, even in churches where stained glass had been used, are often found concealed under whitewash, and every year brings some to light in our own country.]† Similar works in a ruined state have lately been discovered in the choir of the cathedral at Cologne. These are now to be replaced, Cornelius states, by Professor *Steinle*, and the general

* For a description of *Pordenone's* principal fresco, the cupola of *S. Roeco* at Venice, see *Boschini*, *La Carta del Navegar Pittoresco*, Ven. 1680, pp. 90—94.

† Notes on *Du Fresnoy*, Note LV.

‡ The works of *Corregio* in fresco are here referred to merely to show that the practice of that method has no disadvantageous influence on the practice of oil painting; but the cupolas of *Corregio* at Parma are by no means favourable examples of the durability of fresco. Their decay appears, however, to have been owing to the former dilapidated state of the roofs and the penetration of damp, as the lower figures are better preserved. The fresco in the tribune of *S. Giovanni* was destroyed in enlarging that part of the church; part of the principal group, the Coronation of the Virgin, was fortunately saved, and was inserted in the wall of the library at Parma. It is in perfect preservation, and is one of the noblest works of the master.

* As the opinion respecting the necessity of using lime that has been long kept is frequently repeated in this paper, it may be necessary to state that other German and Italian fresco painters do not consider it essential to keep the lime longer than ten or twelve months.—See the remaining papers in the Appendix.

† Preston, Dartford, Rochester, the Chapter-house Westminster, &c.

style to be adopted will correspond with the architecture, although the forms and draperies will be treated with a due regard to the best examples of art.

Cornelius thinks that Westminster Hall might be decorated on the same principles, with a like attention to the character of the architecture. He considers that as the walls of such buildings were sometimes hung with tapestries, they could be quite as consistently adorned with paintings. It is to be observed that in the Hall of Constantine in the Vatican, painted by Giulio Romano and others from Raphael's designs, the edges of the frescoes are made to imitate the appearance of tapestry; this treatment is also observable in some of the ceiling paintings of the Vatican, though differently contrived according to their situation. But Cornelius thinks no such approximation to the effect of hangings necessary, since paintings were quite as common as tapestry in ancient Gothic edifices. He considers the questions as to the appropriate style of sculpture and painting for Gothic buildings to rest precisely on the same grounds, and assumes that the artists of the thirteenth century would have added better ornaments to the architecture of the period if they had possessed the skill. He considers it nevertheless essential that a certain congruity and harmony should be preserved, less dependent on association than on general principles. He thinks that the style of some Florentine masters of the fifteenth century would harmonize well with Gothic structures of an earlier date or character.

It is here to be observed that the question of the adaptation of the style of art to the architecture is connected in the mind of Cornelius with that of the general expediency of returning to those severer principles of design which, it is acknowledged, first led to excellence in Italian art. With these views he connects the consideration of the nature and capabilities of fresco, as a means of ensuring attention to the elements of form and composition. The founders of the present German school, as is well known, at first proposed these principles and methods not as an end, but as a means which it was hoped would again lead to important results. But the attempt, according to the eminent artist so often quoted, was at the outset universally condemned. When a few individuals (with that artist himself, Overbeck and Veit at their head) began the revolution which they have now rendered comparatively popular, they had to encounter the most violent opposition and the keenest ridicule from their own countrymen; and even when, after years of perseverance, they had succeeded in gaining some favour at home, it was long before foreigners acknowledged their merit. Cornelius dwells on these circumstances in recommending the style above alluded to.

There are other considerations connected with the application of painting to Gothic architecture particularly, on which Cornelius was consulted, and which may not be undeserving of attention. The available spaces for painting in Gothic buildings are supposed to be unfavourable; the pointed arch, sometimes introduced superficially on walls, and the acute forms produced by the simplest groinings in ceilings are, it is remarked, difficult to fill satisfactorily. It is here necessary to bear in mind that the taste for this style of architecture declined in Italy much earlier than in the rest of Europe, and hence the examples of celebrated paintings in Gothic churches are rare: the works of Cimabue and other early Italian masters as Assisi, and those ascribed to Giotto in the church of the Incoronata at Naples are, however, cases in point, and had Gothic architecture continued to prevail in Italy, higher examples, it may be assumed, would not have been wanting. Cornelius does not admit that there is any unusual difficulty in adapting painting to the compartments of Gothic architecture. [It may be readily granted that all ceiling painting is difficult to contrive and execute, but no Gothic roof, assuming the groining to be simple, could present such difficulties as Michael Angelo had to contend with, in the angles of the Sistine chapel (the architecture of which is not Gothic), where the figures are painted on a projecting ridge formed by the meeting of two curves. The celebrated foreshortened figure of Haman is painted on such a surface. A portion of the ceiling in one of the Stanzas of the Vatican, presents similar difficulties.] The more florid style of Gothic may be acknowledged to be unfit for pictorial decoration on a large scale; its surfaces being so crowded with ornamental panelling that little space remains for pictures.

Another objection to the application of painting to Gothic architecture, is the use of stained glass. A decoration so suitable in many instances to Gothic windows, is incompatible with the due effect of paintings on the walls, the colours of which require to be displayed by a colourless, and at the same time a sufficient light. This objection is met by the consideration that stained glass is not desirable nor usual in all Gothic buildings, to the extent to which it was employed in those of a sacred character. Its application elsewhere was generally less profuse, and might be so contrived as not materially to interfere with the quantity or quality of the light. In answer to a question on this subject addressed to Cornelius by letter, he replies: "The church 'in der Aue,' at Munich, which has painted windows, is not adorned with frescos, but the church of St. Francis, at Assisi, shows how painted windows and frescos may be combined. The paintings discovered in the cathedral at Cologne were without doubt executed immediately after the completion of the choir."^{*}

Fresco as compared with Oil Painting.—Cornelius is decidedly of opinion that fresco should be preferred to oil painting for the decoration of the new Houses of Parliament. In pronouncing this opinion he is of course not alive to any of the considerations which would weigh with English judges respecting the present ignorance of the process of fresco in this country, and the comparative mastery of our oil painters. In no circumstances probably would he prefer oil pictures to fresco, in which he has for many years been constantly engaged, and in which his taste has been formed. He, however, supports his preference (at least with regard to certain applications of painting) by argu-

ment and example. He maintains that fresco is on every account fittest for monumental, permanent works in public buildings in which painting is to be considered as the handmaid of architecture. The Italian masters, he observes, were always fully impressed with the necessity of adapting their works to the effect of the architecture, so as to make one harmonious whole. The nature of fresco fits it for such a purpose. It is indeed impossible to produce that illusion which is considered so desirable in oil pictures—the same depth of shade is not in the artist's power; but this very circumstance, while it compels attention to composition, colour, and form, renders fresco more directly appropriate for strictly decorative purposes.

On no point is Cornelius more decided, than on the necessity of placing a given series of frescos under the controul of one directing artist. This appears to be quite compatible with the employment of many such directors, by subdividing the works; but he thinks it most desirable that in one complete series there should be a congruity of style and general execution. In Munich, where great experience has now been gained in these undertakings, several independent masters have formed scholars to work in their style, and these have been ultimately employed on original works. This gradual education of scholars is observable, if we follow the career of Cornelius himself. For example, when employed in his first work in Munich (the frescos of the Glyptothek) the cartoons were all the work of his own hand; the assistance he received was only in the execution of the paintings. In the Pinakothek his sketches and small drawings sufficed for his pupils to prepare some of the cartoons, and lastly in the Ludwig-Kirche the invention even of some subjects was entrusted to a scholar, named Hermann.^{*}

No new modes of cleaning fresco have been devised in Germany. To a question on this point addressed to Cornelius by letter, he replies:—"The London smoke may, undoubtedly, have a disadvantageous effect on frescos; but with a due warmth—for example, by the introduction of warm air or warm water in tubes—I am of opinion that, in the situation where the new buildings are, no particular evil effects are to be apprehended. If, however, after fifty or a hundred years it should be found that the dirt had accumulated to a great extent, the surface could be cleaned with bread. The mouldy appearance which sometimes shows itself is to be removed with a wet sponge. The mouldy efflorescence which appears in some cases may be owing to saltpetre in the walls: for this there is no remedy; but, on the other hand, it never appears when the walls are built with well-seasoned and dry materials. In the Munich frescos no saltpetre has shown itself." [An artist of Rome, Cavaliere Agricola, has been lately employed to clean the old frescos in that city; he has published the result of his experience, and his report, which has been procured, would be among the documents to be referred to in any future inquiry relating to the modes of cleaning fresco. The method adopted by Carlo Maratti, in 1702, as I have elsewhere remarked, is also preserved.]

Time necessary for the execution of works in Fresco.—The whole scheme and invention of a series of frescos should not only be settled, but all the large drawings made by the time the building is ready; for the work can then advance rapidly. Supposing the present buildings to be ready in seven years from this time, Cornelius says it is time to begin the designs. The German artists, expert as they are in drawing, always take some years to prepare their cartoons. Cornelius's cartoon for the altar-wall of the Ludwig-Kirche at Munich was executed in Rome: he went there for the purpose. If Westminster Hall, or any other building already in existence, is to be adorned with frescos, the wall should be prepared with the first rough coat of mortar at once; for this ought to be on the wall, if possible, for some years before it receives the final preparation immediately before painting, unless very old lime be used in the first instance: but even in that case, six or twelve months should elapse before painting on it, to give it ample time to harden.

The practice of Fresco painting.—The Cartoon.—It may be assumed that it is impossible to retouch a fresco painting to any extent. The portion of the work undertaken in the morning must be completed during the day. The partial remedies and contrivances in case of unavoidable delay or accidental defects will be hereafter considered.

Hence every part of the design must be defined in preparatory studies: the fresco is, in fact, a copy from these, the forms being traced on the wall from drawings the full size. [Cartoons of the kind prepared for fresco (that is, without colours) may be seen in the National Gallery; namely, those at the head of the staircase, by Agostino Caracci.] When the painting is to be very large, and it is found inconvenient to prepare a cartoon of the same size, the drawing may be made half the size: or, the whole composition of the full size may be divided into two or more cartoons: [thus Raphael's cartoon for the school of Athens, preserved in the Ambrosian Library at Milan, contains the figures only, without the architecture.] It is scarcely necessary to observe that the cartoon itself is, in the first instance, generally enlarged from small drawings of the whole composition, with the aid of careful studies for the separate parts. The following is the mode in which Cornelius prepares and fixes his cartoons. A strong cloth is stretched on a frame as it is to be prepared for painting; paper is then firmly glued on the cloth. When this first layer of paper is quite dry, a second layer is carefully glued over it in the same manner. The edges of the separate sheets are a little scraped, where they overlap, in order to preserve an even surface. The surface is then prepared for drawing with size and alum. The drawing is made with charcoal, and, when finished, is fixed by wetting the back (the cloth) with cold water and then steaming the drawing in front. The effect of this last operation is to melt the size a little, thus fixing the charcoal.

A finished drawing of the full size being thus ready, the outline is traced from it on oiled (transparent) paper: if the finished drawing is half the size,

* Without reference to the style of the architecture, the highest authority for the union of stained glass, to a certain extent, with paintings on the walls, is that of the Stanze of the Vatican, the windows of which were enriched with figures of angels supporting the papal arms (those of Julius II., and Leo X.), by the glass painter, William of Marseilles, at the very time when Raphael was painting the frescos of the same rooms. See Vasari, Vita di Guglielmo da Marcilla.

* The public spirit of the German artists is apparent in the circumstance of Cornelius himself now undertaking to superintend the execution of Schinkel's designs in Berlin, with scarcely any addition of his own. His own first original work in that city is to be the decoration of a Campo Santo.

† Presented by Lord Francis Egerton. Agostino Caracci assisted in the frescos of the Farnese Palace, and the two subjects in question were, it appears, designed and executed entirely him. See Lanzi, v. 5, p. 74. and Malvasia, v. 1, p. 439.

it is enlarged by squares to the full dimensions, portion by portion: in this case the paper on which it is copied should be moderately thin, for the convenience of tracing on the wall. A part of this "working" outline (as much as can be finished in one painting) is now nailed to the wet wall, and the forms are again traced with a sharp point, which makes an indented outline through the paper on the soft plaster. The "working" drawing is generally destroyed in this operation. [The following is another mode: the paper to be applied to the wall is placed behind, and in close contact with, the finished cartoon; the outlines of the latter are then pricked, and the operation necessarily leaves a similarly pricked outline on the paper behind. The next process is to pounce the pricked outline of the latter, when fastened to the wall, with a little bag of black or red dust: this leaves a dotted outline on the wall. This method is sometimes adopted for small works, as the surface of the plaster thus remains undisturbed.] The first mode—tracing on oiled paper and then again from it to the wall—is, however, generally preferred, since it ensures the best and most decided outline, while the finished cartoon may be preserved uninjured. In many celebrated Italian frescos the indented outline, produced by tracing, is apparent.*

It has been already observed that the fresco is a final operation; any considerable alterations that may suggest themselves when the cartoon is completed must be made on the cartoon, or rather on additional pieces of paper fitted upon it.

[One of the most interesting examples of the nature and extent of the alterations that may be introduced in a composition prepared for fresco, is the cartoon, already referred to, of Raphael's School of Athens. The changes are mostly additions. The figure of Epictetus, represented in the fresco sitting in the foreground on the left, leaning his head on his hand, is wanting in the cartoon. This figure was added to fill up a vacant space, and thus the change, though a considerable improvement, involved no inconvenience. Some less important alterations in the same fresco, such as covering the head of Aspasia with drapery instead of showing her flowing tresses (for thus she appears in the cartoon), might have been made on the wall without any change in the drawing. That this cartoon was the identical one which served for the execution of the fresco is proved by the exact conformity of every part, except the additions above mentioned, with the painting.]

Beside the Cartoon, in which the forms and general light and shade are determined, it is desirable to have a coloured sketch of the whole composition, for it is almost as impossible to change colours as forms after the fresco is done. In general, the German painters are not in the habit of making complete coloured sketches for this purpose.

The Preparation of the Wall.—If the wall to be painted is covered with old mortar, the ingredients of which are unknown, this coat should be entirely removed till the solid materials are laid bare. The rough coat then applied is composed of river sand and lime. The proportions of the sand to the lime may vary in different climates, and the working builder and mason are sufficiently experienced on this point. In Italy, it appears that two parts of sand were added to one of lime; the Germans generally use more sand, viz., three parts to one of lime. The thickness of the coat is such as is generally used in preparing the walls of dwelling-houses. The surface of this first application should be rough, but not unequally so; and the mason should avoid leaving cavities in it.

The wall thus prepared should be suffered to harden perfectly; the longer it remains in this state the safer it will be, especially if the lime used was in the first instance fresh. In that case, two or three years even should elapse before any subsequent operations are undertaken. Among the essential conditions of fresco painting must be mentioned the preparation and seasoning of the lime. At Munich it is made and kept as follows:—A pit is filled with clean, burnt limestones, which, on being slaked, are stirred continually till the substance is reduced to an impalpable consistence. The surface having settled to a level, clean river sand is spread it over to the depth of a foot or more, so as to exclude the air, and lastly the whole is covered with earth. The German painters suffer the lime to remain thus for at least three years before it is used either for the purposes of painting (for lime is the white pigment) or for coating the walls. Cornelius prepared the lime for the Ludwig-Kirche eight years before he painted there. A great quantity is generally kept in Munich, and might, perhaps, be had from thence for works in this country. The late Lord Monson intended to have had lime from Munich for the works which Cornelius was to have done for him at Gatton. The pits or vats in which the lime is preserved are not lined with brick nor protected in any way; they are dug in the mere earth. The lime thus kept is found moist, as at first, after many years. Cornelius said that there might perhaps be no objection to lining the pits, so as to keep the lime clean, but that the usual mode was to slake it and keep it in the mode described.†

The ultimate preparation for painting on the dry, hard, well-seasoned mortar is as follows:—The surface is wetted again and again, with water that has been boiled, or with rain water, till it ceases to absorb. Then a thin coat of plaster is spread over that portion only which is to be painted; the surface of this coat should be but very moderately rough. As soon as it begins to set (in ten minutes or so according to the season), a second thin coat is laid on somewhat fatter, that is, with more lime and less sand,—about equal proportions. Both these layers together are scarcely a quarter of an inch thick. The plaster is laid on and the surfaces are smoothed with a wooden trowel—this is at least Cornelius's practice. Some painters like the last surface (which is to receive the fresco) to be perfectly smooth; one of the modes of rendering it slightly rough is to fasten some beaver nap to the trowel: another is to pass over the plaster in all directions lightly with a dry brush.

* The outlines of Raphael's cartoons are covered with pin-holes. This is very apparent also in the fragment of the cartoon for the Murder of the Innocents now in the National Gallery. Of the cartoons above mentioned, by Agostino Caracci, one (the Triumph of Galatea) has the pricked outline; the other (the Cephalus and Aurora) not.

† The Italian mode, described in another paper of the Appendix is somewhat different.

‡ Professor Hess directs the lime to be kept in pits lined with brick.

The process of Painting.—A portion of the outline is now traced with a sharp point on the plaster as before described, and the painter begins to work when the surface is in such a state that it will barely receive the impression of the finger, and not so wet as to be in danger of being stirred up by the brush: besides other inconveniences this would fill the brush with sand. If the wall has been previously well wetted, the plaster will not dry too rapidly; but if, during the course of a dry summer's day the surface begins to harden too much and no longer takes the colour well, the painter takes a mouthful of water from time to time and sprinkles it over the surface, in the same manner as sculptors sometimes wet their clay models. Much evidently depends on the thorough wetting of the dry mortar, before the last preparatory coats are applied.

In painting, it will be found that the tints first applied sink in and look faint, and it is necessary to go over the surface repeatedly before the full effect appears. But after some time, especially if the surface be not occasionally moistened, the superadded colour will not unite with what is underneath. The change in some of the colours from the wet to the dry state can be best learned by experience, but it is usual to try the tints at first on a brick or tile that absorbs moisture.

After having completed the portion allotted to the day, any plaster which extends beyond the finished part is to be removed, and in cutting it away care must be taken never to make a division in the middle of a mass of flesh, or of an unbroken light, but always where drapery, or some object, of its own outline forms a boundary; for, if this be not attended to, it is almost impossible, in continuing the work the next day, to match the tints so that the junction shall be imperceptible; but by making these junctions correspond with the outlines of the composition, the patchwork which is unavoidable is successfully concealed.

In the next day's operation the surface of the old mortar is to be wetted as before, and care must be taken to wet the angles round the edge of the portion previously painted. This requires to be done delicately with a brush, in order to secure the sufficient moistening of every minutest corner, and also to avoid wetting or soiling the surface of the finished portion. On this last account it is better to begin from the upper part of the wall; for, if the lower part is first finished, the water constantly runs over the fresh painting.

When the painter is unable to finish a portion at once, or is compelled to leave it during the day for a considerable time, the Munich artists have a contrivance which arrests the drying of the work. A board is padded on one side, the cushion being covered with waxed cloth; a wet piece of fine linen is then spread over the fresh plaster and painting, and pressed to the surface of the wall by the cushioned side of the board, while the other side is buttressed firmly by a pole from the ground.

When any defect in the first operation is irretrievable, the spoiled portion is carefully cut out and the process above described is renewed for that particular part. The same remedy is possible in reviewing the finished work, but here again care should be taken that the portion cut out should be bounded by definite lines, for the reason before given. This attention to the nice adjustment of the successive portions of the work, so as to make one whole in the mere execution, is of great importance in fresco painting.

In the finished fresco the depth of shadows is often increased, parts are rounded, subdued and softened, by hatching, in lines of the colour required, with a brush not too wet; the medium then used being vinegar and white of egg. Shade is more easily added in this way than light, but some use crayons made of pounded egg-shells to heighten the lights. It is to be observed, that such retouchings are useless in frescos painted in the open air, because the rain washes them away, whilst the rain does not affect frescos painted without retouchings; of this the paintings on the Isar-Thor at Munich are a sufficient proof. [Cavaliere Agricola who, as before observed, has lately published a report on the Roman frescos, is of opinion that they were retouched with coloured crayons.* Vasari,† however, distinctly says that frescos which were not retouched were least subject to alteration and decay.] Various methods of this kind have, nevertheless, been resorted to by the Munich painters, and Cornelius has mentioned some.

The Colours and Implements.—These details, communicated with all-sufficient precision by Cornelius, need not be inserted here, as they are given in other papers that follow. The colours are chiefly simple earths; no vegetable, and few mineral, preparations can be used with safety, but there is a mode of rendering vermilion durable. The palette is of tin, with a rim round it to prevent the colours, which are thinned with water, from running off. The colours, mixed or ground in water, are kept at hand in small pots. The brushes are of the usual materials, but they should all be somewhat longer in the hair than those used for oil-painting.

† Introduzione, c. 19, and Vita di Antonio Veneziano.

(To be continued.)

MARTIN'S PATENT CEMENT.

Upon visiting the Sun Fire Office now erecting under the superintendence and from the designs of Mr. Cockerell, we were much gratified by the superior execution of the internal ornaments, which so far as the unfinished state of the building would allow us to inspect them, and leaving design out of the question, were singularly neat and perfect. Indeed we have scarcely ever seen mouldings present so finished an appearance. The great objection to panelled walls has hitherto been the very heavy expense consequent upon the employment of such mode of embellishment. The mouldings are run and the walls covered with a cement called Martin's Patent Cement, and present a surface nearly as smooth and hard as glass; it is applied in much the same way as any other cement.

TABLE OF PROPORTIONS OF THE PARTS OF CLYDE MARINE STEAM ENGINES—CYLINDERS.

All the figures which are not represented as feet or numbers are inches.

Names of vessels	BRITISH QUEEN.	DEE and SOLWAY.	DON JUAN.	HECLA and HECATE.	DEVONSHIRE & CAMBRIDGE.	BRUGES.	OBSERVATIONS.
Makers' names	Girdwood & Co.	Scott, Sinclair & Co.	Girdwood & Co.	Scott, Sinclair & Co.	Girdwood & Co.	Caird & Co.	
Diameter of cylinder	76	73	68	60	55½	51½	The sizes of the British Queen given are the sizes of the engines intended to have been put into that vessel by Messrs. Girdwood and Co.; but as they failed before the engines were finished, they were never finished at all. These engines were to have had two slide valves to each cylinder, one on the side of the cylinder next the condenser, and the other at the opposite side of the cylinder. The object of this arrangement was to enable the engineers to handle the engines easily and quickly: in starting or reversing only one of the valves would have been used. The condenser was situated beneath the cylinder, and that is the reason why the cylinder bottom is so much above the sole plate. The space usually occupied with the condenser was to have been appropriated to Hall's condenser, and the condenser beneath the cylinder was to have been used in the event of Hall's condenser becoming deranged, or not answering as well as was expected. The main pillars of the framing were to have been of malleable iron, fixed into strong sockets on the sole plate and cuttered through. The whole of the joints in the recent engines of Messrs. Miller and Ravenhill and Messrs. Maudslays and Field are metallic, with one or two exceptions: but in Scotland this system has not yet come into general use. Not one of the engines the dimensions of which are given in the table, is provided with an expansion joint in the valve casing. The transverse joint in some of them between the cylinder and casing on the level of the cylinder cover, it is impossible to keep tight for any considerable time, owing to the unequal expansion of the cylinder and casing when the steam is up but the engine not working. The grease, too, that is apt to fall on the cylinder flange, is unfavourable to a rust joint in this position. The rust is de-oxidized by grease remaining in contact with it for a considerable time at a high temperature. The plan of completing the flat portion of the valve casing above the level of the cylinder cover by a supplemental piece cast on the cylinder, is, we think, the best. Messrs. Maudslays' practice, in some of their recent engines, is to make the flange of the valve casing range with the flange of the cylinder, and then bolt to the top of the valve casing a length of D shaped pipe. This certainly is not by any means a neat arrangement, nor does it, we conceive, afford equal stability to the cylinder faces, as the mode of casting the flat part of this supplemental piece upon the cylinder itself.

ON FRESCO PAINTING.

BY JOSEPH SEVERN, OF ROME.*

(Continued from page 189.)

ON a former occasion (see *ante*, p. 189), I was not altogether aware of the difficulties that fresco-painting might possibly have to encounter in its introduction into England: perhaps my enthusiasm on the subject had a little blinded me. Being seriously anxious for the success of the experiment, I think it better now to review some of those difficulties which architecture, with painting, hand in hand, may have to surmount. But, to lighten a disagreeable task, I propose also to advert to the bright side of the subject—I mean the union of architecture and fresco-painting, as regards invention. It is a melancholy reflection, admiring and loving fresco-painting as I do, for its high capabilities as applicable to England, that from mere caprice it may be spurned by our artists as well as the public. This may arise from the singular apathy which prevails in this country with respect to painting as an intellectual art, as a moral power. Yet when the great simplicity of painting is considered, its universal language, as addressed alike, without the difficulty of translation, to all nations—to the learned and ignorant—to children, to babes—to all—it must be felt as a great power—and one, in this country, never fairly exercised; if indeed it has ever been exercised at all, which I doubt.

This English apathy with regard to painting as a moral power is such, that at this moment I know of nothing but the novelty of fresco-painting likely to recommend it to my countrymen; for, unless it can give "good things and understanding too," it will be regarded merely for its *material* interest, and not as the facile means of conveying a new and solid pleasure in opening the wondrous resources of art, and making painting rank with poetry and philosophy as a moral agent. More money is spent on the arts in England from one end of the year to the other than was ever spent before, or is distributed in any other country, or, perhaps, even in all other countries put together. But, in converse ratio to the money, is the time given to the arts. This is assuredly less than is devoted to any other intellectual pursuit: and here I come to the great evil—an evil for which I see no remedy but state patronage. The generality of English pictures are produced by our artists, without due consideration of the decorum and power of the art, and are of course looked at in the same light by the public; but when once a tone and a taste are given, by Government protection, and its connection with architecture, there is then some hope that these vast annual sums will be properly expended, that our homes will be adorned with instructive ornaments, and a new delight experienced by the English people. Without this, I fear that fresco, with all its capabilities—the good it will do to oil-painting in the education of the artists—the noble way it will call up the splendour of past English history—the opportunities it will give us to vie with foreign nations in the higher branches of art—I fear that all these advantages may be lost, and painting become subordinated to the upholsterer, who will reap the hard earnings of the artist, and take all the credit of his labours. So much we have to fear from the apathy of the artists and the ignorance of the public; for they may go on as they do now, charging each other with want of capacity, until the upholsterer steps in, like the lawyer in the oyster fable, eats up the prize, and gives an empty shell to each!

To avert this consummation, the first experiment must be made in an entire work—in a complete composition, bringing fairly together on a large scale all the powers of fresco, in which it excels every other manner of painting. Thus developed, I am certain some fine point of our history would strike every one by its simplicity and grandeur, two things unknown in our art now. I see, even at this moment, "in my mind's eye" young Richard the Second riding up to the rebellious crowd as their new leader and king, whilst Wat Tyler sinks confounded in death under the heroic blow of the Mayor; then the consternation and doubt in the King's attendants at the result, contrasted with the panic of the crowd—the action taking place in a large open space, admitting the crowd, the horses, and even the buildings of the time. Some such subject, fairly and honestly wrought, would insure the success of fresco. The English have too much love for dramatic history in books not to like it equally in painting, but it must be in a picture suited to them. I cannot but think that the adaptation of fresco to our English purposes and feelings is the only way to extend the sphere of history painting,

as the powers it affords invention are greater than those admitted by oil-painting, and includes so many things in common with architecture. Nay, it is not too much to anticipate the creation among us of a new style of art, since the materials we have to work up and upon seem to be almost untouched. I think I am correct in observing that, as a people, we always search for something like a story in all works of imagination, and appreciate most of all the things which help to illustrate the story. This is an excellent groundwork for the British heroic fresco-painter. I think also, as I have been speaking of our ignorance of high art, I may fairly add, that our love for the other and lower walks of art has not been fairly noticed or appreciated, certainly not turned to account. During my absence from home, I was taught to believe that the English were dull and careless about the arts in every way, showing no feeling but the bad one of mutilating statues and scraping pictures; but my own eyes have taught me that these assertions are untrue. Consider the paying crowds in the exhibitions; is not this a strong example of love for the arts? Count the numbers who visit so respectfully Windsor and Hampton Court; is not this a genuine sign? Nay, take the more humble spectators who congregate and buzz about the print-shops, like "bees about a honey-crocker," and shall we not find in them symptoms of the most ardent love and the most elegant taste, if it were cultivated by education?

Now Fresco is to aid this cultivation, inasmuch as it will extend the art to history, and connect it with architecture; thus giving a purpose and a significance to painting, since I conclude the object of the building will always extend to the subject of the pictures. A succession of subjects illustrating the lives of our heroes will be demanded. The story, for instance, of our Alfred would thus form a kind of epic poem in painting, when done in architectural fresco, since the pictures may be united into a series, not only by the progressive relation of incidents, but by appropriate ornaments still farther illustrating the period. A suite of rooms in this way may be made as one, through which the gazer may walk with the same mental profit as he enjoys in reading history, for they will afford him a kind of animated reading at a glance.

Painting represents only one moment of time, but that moment comprehends the past and the future, since both must be implied to make the present action intelligible. Unless the subject admits of this, all the force of expression and the variety of character, all the costumes, the architecture, and the landscape are thrown away, for all must be seen at a glance, and that glance must take in the whole subject. Hence I conceive painting is the most natural and simple of the arts, and the best suited to convey a moral. How proud shall we feel to see the noble deeds of our forefathers warming up the walls of those buildings which are the result of those deeds! To see our Alfred, when a fugitive, singing to the Danes, and then conquering them—to see him modelling his little ships, and then building up his empire—to see him constructing a lantern and a clock—translating the Holy Scriptures—and compiling the laws of England, which still are standing like the rock of his own immortal fame, even to our days—the second thousand years bringing out their value tenfold. What heroic subjects are there to compare with this? for, while it has all the abstract beauty and sublimity of the true heroic, even to the charms of antiquity, it is at the same time about us—it is the element of the glorious liberty we live in—it is the power which has extended our empire round the world, in peace and liberty, in religion and philosophy. What bosom can be insensible to such deeds, when they are represented on a scale worthy of their grandeur? but this can only be accomplished when painting is assisted by architecture—when it has the aid of grand proportions—when its figures are life-size at least—when its backgrounds are ample—but most of all when the use of the building it adorns has suggested the choice of subject.

It is true that the art of painting is only to be acquired by years of devoted attention, but this does not apply so much to the inventive as to the mechanical part. The story told by a picture should be intelligible to all. I can well remember, when a boy, the strong impression made on me by the cartoons of Raffaello, which raised an interest and curiosity in my mind that led me not only to read the particular chapters explaining the important scripture subjects they present, but also to begin anew the entire reading of the Bible, with the first love I felt for it, and certainly the first intelligence about it. To those who infer that no benefit can come from the fine arts I would address these remarks, for is it possible that when Raffaello has given us those immortal pictures, more than sermons, that we should still look down on the art as a thing merely sensual? Is it possible that the dying Ananias, extended on the ground before the Apostles, who call down the vengeance of Heaven on his uncharitable lie—whilst even, when his horror-struck friends fall back from him, his unconscious wife behind is still counting

* We are indebted for the continuation of this paper to the *Athenæum*.—EDITOR.

the money which is purchasing for her the same fearful doom—can be beheld by any religious man without awe? If so, I am sure he would sleep over the best sermon on the subject.

The true object of historical painting is to compress into one compact whole all the important points which in books are scattered up and down through many pages, so that the entire power of the subject shall strike at a glance. This is completely done in Raffaello's splendid composition of St. Paul preaching at Athens. Here the whole subject, which in the New Testament occupies a long chapter, is concentrated in a single look. We enter the picture by the steps whereon the Apostle is standing with upraised arms, communicating that divinity which inspires him. We distinguish the various Athenians congregated about him. Dionysius and Damaris in the foreground are in the moment of conversion to the Christian doctrine of the resurrection, and the similarity of their attitude to the Apostle himself at once implies that they believe his doctrine, and receive the Holy Spirit. Near them is the Stoic, who ponders over the resurrection of the body, more puzzled how it can be than questioning that it is. The Cynic stands next leaning on his crutch, and listening with an ironical sneer. The elegant Epicurean smiles incredulously. Beyond are congregated the disputants of the academy, lost in their own opinions, save those of Plato's school, who show an elevated attention. Contrasted with this is the rankling malice of the rabbi—the magician's mysterious glance. And all these various persons are assembled on the Hill of Mars, as described in the 17th chap. of the Acts of the Apostles. Now it must be evident to any one who will be at the pains to examine this sublime work, that no description can produce the instantaneous effect of seeing all the persons brought together in one scene. Is it possible that a work approaching so near to the sacred description itself, and partaking of its sacred character, should not claim our deepest attention? Yet it rarely gets any attention. At Hampton Court may be seen crowds passing heedlessly through the room which contains these, the finest works of Raffaello, who have perhaps bestowed hours of attention on everything else. Why is this? It is the mistaken locality. It is that these works, which are of the most sacred character, should be shown in a sacred place, which would inspire a devotional feeling, necessary for the entire understanding as well as the feeling of their thoughtful beauty; for how few persons are there, even amongst the high and educated, who are able to abstract themselves so suddenly from the profane so as to appreciate these PICTORIAL SERMONS, in the midst of art's gay profanities, which on every side surround them. It is too much to expect that Raffaello's cartoons should duly arrest the attention, placed as they are at Hampton Court. I remember another example of the truth I would express. The late gifted historical painter, Hilton, produced a fine work of the Crucifixion, which was admirably painted, designed, expressed, and on a sufficiently large scale. This picture was exhibited at the Royal Academy, and excited little or no attention; it was not even (as I am assured) noticed at the grand annual banquet, when all the most distinguished personages of the state are present. This I also find natural and proper; for how was it possible to look in a right spirit on the agony of our dying Saviour, in the midst of a splendid and social festival, or even in an exhibition made up of happy smiling ladies and courteous gentlemen? Now this brings me to the great good of painting being united to architecture, in the introduction of fresco, where, in becoming part of the walls it must of necessity partake of the object of the building. Of this good I will mention one singular and signal example. That noble picture by Leonardo da Vinci, in the Milan Convent of Santa Maria della Grazia, representing the "Last Supper," is almost unintelligible to us as a composition, without due consideration of its locality. This is admirably pointed out by Goethe. He saw the refectory, with all its religious members at their solemn meal. Opposite to the picture stood the prior's table, the monks sitting down the hall on the right and left; so that you will perceive at once that the painter in the composition endeavoured to make his great work fill up characteristically the other end of the room. No doubt he made it correspond in everything—the table-cloth with the corners tied up, the dishes and the drinking-cups of the time and place. By this interpretation is answered the objection continually made, that the figures are all sitting on one side of the table, for the monks always sit so in a refectory. I cannot bear to allude to this wondrous work without speaking of its deep and impressive character. When you stand before it you almost hear the tremendous secret which our Lord declares at the supper—"I say unto you, one of you which eateth with me shall betray me!" Now who would believe a picture could represent such a moment, unless he had such a work? The dreadful accusation falls upon every one save the beloved disciple John, and at once calls forth the varied expressions of men accuse

of such treachery. The gazer may easily make out each Apostle by his individual character and expression, as each one endeavours to show his innocence of the charge. Judas is known by the money bag, and by his knocking over the salt. What an appropriate subject for a refectory! The well-known story told by Wilkie of a similar picture in Spain, will serve to show the great moral of such a work. An aged monk, observing him unusually interested, said to him, "Ah! you cannot feel the interest I feel in that picture, for I have sat before it at my meals some seven and forty years, and such are the changes which have taken place in Spain, so many companions have come and gone in the time, everything changing but that picture, that when I look upon it and its solemn company, I almost believe in truth they are the substance, and we but the shadow." There can be no doubt that Hilton's picture of the "Crucifixion" lost as much as Leonardo da Vinci's gained, by the locality and its associations.

Following out the same principle, we may thus have pictures adapted to the church, the palace, the theatre, the exchange, the hospital, and even to the private dwelling. Each will suggest its own just and proper association to painting. I am certain that the art, in its highest destinies, is greatly dependent on architecture, which best awakens those associations necessary to its appreciation.

Again, are we not dependent on painting for the precise representation of places which we have never seen? Can anything be dearer to us than painting in its remembrance of the illustrious dead, or those who were dear to us? Are we not dependent upon it and sculpture for the very existence of antiquity? have we not the most distant climes at our fire-sides, and the people of the antipodes made our very companions? and yet what I have enumerated, are but the limited performances of painting, and in no way to be compared with its achievements when it raises itself to the representation of history on historical walls. Is it not wonderful to have realized to our sight the actual scenes of the past;—to have the persons of bygone ages alive again, their proper selves, and in full action, expressing their noblest deeds? Were the art realizing such powers, such delights, a new discovery, it would be crowned as the immortal flower of the world—as a supernatural power, re-creating the world which is past. But, dulled and kept down as it has been by its servitude to common uses, in a commercial and a political society, it only now begins to look up for emancipation in the midst of general improvement. It begins to spurn the prison walls of an exhibition-room—it longs, it demands to be free like the other arts. We used to be told that the African slave was an inferior being, and only fitted even for servitude by blows instead of laws; by a like injustice has the art of historical painting been depreciated in this country to a mechanical level, worthy only to point out the alehouse and the gin palace.

But are not those who bring forward such charges wilfully mistaken? Can such works as the cartoons of Raphael be passed over with indifference? have they not a claim on our sacred sympathies? Are we not rejecting in part our blessed religion, when we reject this powerful resemblance of it? for how can our senses receive the impression of the one and not of the other? I tremble at my own rashness in saying this; for in this country, if there are works of art in a church, we are not allowed even to look on them. In our cathedrals rails and men are employed to prevent us from taking more than a glance even of those monuments erected at the cost of the nation. We may take a hurried look, in the week days, but are never allowed to read an inscription, or to linger on our way. Such a system is only worthy a conquered people, whom it is feared to inspire with their nationality; such things are intelligible in Poland, where it is thought expedient to extinguish even the native language, but I cannot imagine the object here. I would fain hope that a pictorial Wilberforce may rise up with fresco painting, and emancipate us from these slavish customs, by opening the public buildings, even to the churches, and showing the public monuments freely. Here would be a new and powerful source of education to an inquiring people like the English;—the government, the church, the laws, and the people, would be thus brought nearer together by the arts; and in showing how many illustrious individuals have arisen from the lowest ranks, the most powerful incentive would be offered to the ambition of all endowed by nature with genial impulses and generous feelings.

Another slavish prejudice to be done away with by the union of architecture and painting is, our narrow-minded custom of allowing a man to do, or to understand, only one single thing, when the services of Professors generally are required in divers things. Professors may acquire knowledge, but woe betide them if they attempt aught else but the one particular thing which they profess! For this I cannot account, as in all ages—save our own—a man useful to the public has been expected to possess a kind of

universal knowledge to assist him even in his own particular branch, so that he might be at the public command on any emergency. It would seem very odd now, if the State were to call on the Duke of Wellington to take his brush and commence the fresco painting in the new Houses of Parliament; and yet such a call was not uncommon in the fifteenth century. We hear of Michael Angelo summoned from his labours in the Sistine chapel, to prepare without delay the fortifications of Florence, then expecting a siege. We hear also of Leonardo da Vinci, on being invited to paint for the Duke of Milan, beginning his labours by making canals and bridges; and yet, I apprehend, his sublime picture of the Last Supper did not suffer from this abstraction, for it still remains a miracle of art; or that Michael Angelo's fortifications did not help the less to save the city, although he was painting fresco just before at Rome. This universal knowledge is one of the characteristics of the fifteenth century all over Europe. We find similar examples in our own country in the time of Elizabeth, particularly in the class of soldier-poets, and such like men, even music being included in the accomplishments of a complete gentleman. I do not insist now on the necessity of possessing this variety of power; but I would declare, as regards painting, that our present slender circumscribed knowledge can never produce historical painters, or even their patrons. It must be universal knowledge and love of the arts, not only as regards itself, but as regards its connexion with all other arts and sciences. I want to see my deserving countrymen, the English painters, ranking with the best, and British painting arm-in-arm with poetry and philosophy, which it is not now, in place of grubbing among the mechanical trades, with an exhibition room here and there, as "a house of call for painters and glaziers." The liberal encouragement of painting must be advanced, not by our painters shutting themselves up and prowling about with it a secret, save on the temptation of a five-guinea lesson—no; the casket must be unlocked and the key thrown away, and the public instructed in the principles of art. There are no secrets in art; though art is not to be understood without an effort on the part of the public, and is only to be acquired by artists after long years of ardent and sincere study. The greatness of painting must be in its difficulty, and not in its secrecy. It must be in its principles and not in its vehicles; the public must become, as it were, a scholar to the painter. And why not? Why should not the artists themselves try to mould and form that love which, I am certain, exists in the English people, into something like knowledge?

In the education of painters, fresco will exercise all these good influences, inasmuch as it tends to raise them to a true sense of the universality of painting. It must give them, in a pecuniary point of view, the sustained though moderate reward of years of constant employment, instead of the intoxicating, lottery, chance system of the present day. We shall now have the excellent old Italian plan of master and scholar, as in the production of such extensive works many must be employed, and the result will be advantageous to both; this we know was the greatness of Raffaello, whose scholars partake his fame, and so on down to Rubens, and his scholar Vandyke.

Another great result will be to emancipate the art from the trammels of booksellers, who, for more than half a century, have made inventive painting subservient to their speculating purposes as a mere trade. This has kept historical art back in comparison with the many things in which England surpasses the rest of the world; for what can be more servile than the vicious system of ornamenting books, in which the greatest English painters have exhausted and consumed their minds with little fame and less fortune? We have but to point to Stothard as a sad example; he is said to have produced some five thousand inventions in this way! The art has sunk under such baneful influence, and when pandering to the book trade in Annuals and such trash, has ceased to be worthy the name of painting. This state of things does not exist anywhere but in England, and is one of the reasons why we have not been able to make another grand age of art. But our painters must now turn their attention to the ornamenting of buildings, and not books.

The State itself must deal in painting and engraving, and directly reward the artist, if it desires to have art that shall be worthy the English name. This may be done with the outlay of comparatively small sums, indeed it cannot be by the actual money expended, so well as by the direct intercourse of the highest personages in the country with the artist, by a kind of friendly and cheap patronage (if I may so express it), whereby the artist is drawn out of his own narrow circle, and paints not only his own mind, but the mind of his patron. This can only be done effectually in national subjects, and I know well that the Munich artists have always worked, and prefer to work, for their intelligent King, at a moderate rate, to being employed at double the sum by unintelligent persons. Even as regards his fame, the

artist is content on the score of being employed by his sovereign. It is a great mistake in this country to suppose that the encouragement of the arts by the State would be an expensive thing. To get private patronage the English artist is obliged to make an expensive tradesmanlike figure—this not only takes up half his time, but it takes all his money; whereas the simplicity of his life, were he publicly employed, would enable him to bestow double the time on his works, give them, of course, more study and perfection, and create a higher style of art. No doubt, the true reward of an artist is the interest his patron takes in the work. Do we not hear of the restless anxiety of Pope Julius to see Michael Angelo's unfinished paintings? Did not the Emperor Charles V. find time, amidst his active life, to careen Titian, and learn the art from him? And thus it was with Da Vinci and other great artists, whose inventions were quickened, and whose patience sustained, by such an honourable sympathy. For how can an artist excel in a work "where dawns the high expression of a mind," if, when complete, it is to be received into his patron's house like a chair or a table? Pounds, shillings, and pence can never stand for painting, sculpture, and architecture; we must have patronage, study and love. In a country where the historical plays of Shakspeare are still listened to, and where the people never tire of hearing Handel's oratorios, there can be no despair of historical painting being encouraged, when it is properly put before the public, for it requires as great a mental effort to relish the one as the other. English painting is far behind these. We are in it what the ancients were in geography, when they believed the earth to be a plane surface. We are afraid to go to the real boundaries of art, and so we coast it along, like cowards, from place to place, as though there were no such thing as the loadstone of art—as a painter's compass. Let us look for remedy in enlightenment. Fresco is the fearless guide, and, with design for our helm, we shall soon be gloriously sailing on the independent sea of art.

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.

LECTURE X.—ON THE UPPER WORKS OF RAILWAYS.

This lecture was on the Upper Works of Railways, which term, the Professor stated, was intended to comprehend everything above the bed or formation level of the roadway—viz., the gravel, broken stone, or other road material. technically called the "ballasting;" the stone blocks or wooden cross sleepers, laid thereon; the chairs and rails, and their fastenings, as attached to the stone or timber supports; and the boxing or filling up of the road material around these supports, when the railway is finally laid to the proper gauge, range, and level—the whole of the materials and adjustment forming the "upper works"—an expression borrowed from the German *oberwerke*. The depth from the road-bed to the level of the rails, of all these parts, as permanently laid together, is seldom less than two feet. when a good way is to be insured; the principle to be observed being to have the ballasting of such a material and nature that water will percolate freely through, as clean gravel, cinders, quarry rubbish, coarse sand, &c. The word "ballast" is a northern provincial term. Some of the first railways were introduced into the vicinity of Newcastle-upon-Tyne, Shields, and the neighbouring coal shipping ports, and it being found necessary to have a bed or layer of some material, to receive the railway track, the same not to be retentive of water, the gravel brought by the colliers from London as ballast, and accumulated in hills or spoil-banks near the sides of the harbours, was found to answer the purpose very well; the expression has since become common for whatever other material was similarly used for laying railways. Mr. Vignoles observed that a great number of other technical words now in common use, when treating on railway works, were provincial terms, chiefly from the north of England. When the bottom of cuttings, or top of embankments, are of soft material, it was recommended to make a kind of pavement or hard layer, on the forming level, below the ballast. On embankments, until they became well consolidated, this pavement would not perhaps be conveniently put in; still means should be contrived to carry off the water quickly from the surface, and the Professor insisted much on the free introduction of blind, or French drains, of broken stone, among or under the ballast, connected with the open side drains, which should never be omitted in cuttings; on embankments these cross rubble drains should be free of the road-bed, with water channels down the slopes, of sods, or more substantially formed if needful.

The bed of the railway having been prepared on the above principles, next came the consideration of the railway itself. The substance first used for this trackway was wood, and afterwards a metal rail, plated on the wood: after 200 years' trial of different systems—for so long was it since the first

colliery wagon-ways were introduced—the Professor observed, we are just coming back to the original form and material as best adapted for the purposes of a railway—viz. timber laid longitudinally. When blocks of stone are used to support the chair and rail, weight seems to be sought for as desirable, and the general cubic contents of such blocks as are considered proper for a good way are about five cubic feet—viz., 27 inches wide, and a foot thick. When cross bearers of wood are the supports, each sleeper, as it is termed, contains about two cubic feet of timber, being about seven feet long, with a transverse section of 40 square inches, being full eight inches broad, and averaging five inches thick. The intervals at which the blocks or sleepers are placed vary from three to five feet, according to the weight of the rail or of the load. With these descriptions of supports, it becomes generally necessary that a chair or saddle be attached thereto to receive the rail, which is seldom fastened directly either on block or sleeper, without the intervention of this contrivance of a chair, unless when the rail is made wide and flat at the base. Such shaped rail is now much used on cross bearers of wood for temporary railways, by contractors, while executing works. Mr. Vignoles said this form of wrought iron rail was first introduced nearly 12 years since on the St. Helen's Railway, by some contractors, at his suggestion, and the same rails were lately in use by the same persons, and still good and serviceable, after continued use. Of late it had been recommended by many engineers—among which Mr. Vignoles believed he was among the first—to lay down the railway bars on bearings of timber, disposed lengthways in the direction of the way, and upon which the iron had a continuous bearing, instead of having it supported at intervals (either with or without chairs), as was the case when blocks or cross timber bearings were used. In describing the different modes of laying rails, the Professor observed that the heavy stone blocks being packed around, or boxed up with ballast, kept the rails in place—that the cross sleeper having both rails attached thereto, the gauge or breadth was preserved; with the longitudinal system of bearings, the parallelism was retained by cross ties of wood, with tenons, and sometimes by rods of iron with screw-ends and nuts, and occasionally with both. It was necessary thus to provide for preserving the breadth of the railway, for, as the carriages and engines work along the rails with a wriggling motion, there is always a tendency, by the lateral action of the flanges of the wheels, to push the road out of gauge. Mr. Vignoles mentioned the two new lines added on the south side of the London and Greenwich Railway as the latest examples of longitudinal timber bearings; but he observed that, as the great point in this system was to insure that the rail be firmly attached to the wood, to prevent any vertical play, he considered a more effectual method might have been there used, so as to have the iron continually united to the timber, on a plan which he had tried with success, and to which he would presently advert. When iron was first introduced for railways, it was for a long time merely a plating of metal on the edge of the wood rail, on which plan, with iron bars of greater or less weight, many of the lines in America had been laid.* Cast iron being next introduced, the system of fastenings was necessarily changed, and the original longitudinal timbers abandoned for cross sleepers, or isolated stone blocks. The rails being cast in lengths of three or four feet, it was found expedient to prepare some contrivances to receive and fasten the ends together, and this was the saddle or chair. Some of these iron rails were cast deeper in the middle, and, from their shape, got to be termed “fish-bellied,” this form being probably adopted with the idea of obtaining uniform strength; though, for railway purposes, the position of this increased depth was the reverse of that given to bearers intended to resist quiescent weights. From the action of the moving weight, however, upon rails with so many joints, they soon got out of order. Wrought iron was then introduced, to get greater lengths; the first of these were rolled at a considerable expense of useless ingenuity into the same form as the fish-bellied cast iron rails, the length of 15 to 18 feet being divided into five or six flat ellipses. On most of the lines where this description of rails was first laid, it has been found necessary to take them up, and replace them, as they were found to break at a short distance from the points of support. Mr. Vignoles stated that he had, from the first, decidedly set his face against this form of rail, and argued for and introduced rails with the same section throughout their length—since commonly styled *parallel rails*, as distinguished from the “fish-bellied rail,” adding 10 lb. to the original weight of 35 lb. to the yard, by putting on a lower rib or web, on the principle that gave such additional stiffness to all beams; this lower web was increased in size from time to time, until, in a special report to the London and Birmingham Railway, Mr. Vignoles recommended that the upper and lower webs, or buttons, should be made precisely alike, to allow the rail to be turned up or down, or in either direction. This form was, however, first actually laid down by him on the North Union Railway, and its advantages in the above respects have already been appreciated and applied: these rails are about 65 lb. to the yard. The Birmingham Company decided finally on adopting this form, increasing the

weight to 75 lb.; and, where chairs are used, it is now almost exclusively employed, the weight being sometimes increased to 78 or 80 lb. per yard. With the increase in the weight of the rail, the intervals between the supports also gradually increased from three to five feet, but with bad effect, as the expense of keeping a railway in order with the longer bearings (as the technical phrase is) was very much augmented; and, on the London and Birmingham Railway, intermediate supports had since been introduced, where the original bearings were five feet. Mr. Vignoles stated it as his opinion, deduced from considerable experience and observation, that where chairs and supports, at intervals, were used, he considered a 60 lb. rail, with a 3-feet bearing, better than a heavier rail with a longer bearing. Blocks, he observed, were, however, nearly exploded as supports; the cross sleepers and chairs were still preferred by many engineers, but it was certain that the closer the supports—that is, the shorter the bearings—the less the cost of maintenance, and hence the inference, which experience everywhere confirmed, that the continuous supports were best of all. In respect of fastening the chair to the block or sleeper, and the rail to the chair, it was now almost universally admitted and acted upon, that compressed wood was much preferable to iron spikes, bolts, or keys. Mr. Vignoles introduced a number of drawings, and described a variety of diagrams, illustrating the various shaped rails and chairs, and modes of fastening adopted, and drew comparisons as to the advantages and cost of each. In reference to what he had before stated of the disadvantageous method hitherto pursued in fastening rails with flat bases to continuous timber bearings, by spikes or screws, the Professor said that such a mode seldom continued to hold the rail close down to the timber, and there ensued a certain quantity of vertical play of the rail on the wood, often accompanied with a good deal of rattling, and in the end, the head of the bolt or spike was absolutely jerked off. Mr. Vignoles said that the only effective fastening was that used with Evans' patent rails, which had a slit or groove of a dove-tail shape (in cross section) rolled for the whole length of the rail in the bottom; bolts, with similar-shaped heads to fit, were passed into this groove, and dropped at the necessary intervals, through holes in the longitudinal timbers; the bolt terminated in a screw, and a washer and nut being put on, by means of a spanner, the nut drew down the rail closely to the timber. Mr. Vignoles stated that he had had a considerable length of railway thus laid, which had been done some time, and the rail had remained close down on the wood without any play, or getting at all loose. He concluded this lecture by stating that in the next he would endeavour to draw a comparison between the modern heavy rail and chair and fastenings, as used with cross timbers laid at intervals, and the rail and fastening, as above described, to be laid on longitudinal timbers, and having a continuous bearing thereon.

LECTURE XI.

In resuming the subject of the Upper Works of Railways, the Professor said he would enter briefly into the consideration of the strongest form of rail, after explaining those points applicable alike to cast and wrought iron bars. First, a certain breadth was required for the bearing surface of the rail, for the wheel to run upon, and this breadth should be such as not to be likely to produce improper action or grooving, in the tire or tread of the wheel, and, at the same time, not to be increased so as to make the rail needlessly heavy; there must also be a sufficient depth or thickness of that bearing surface, to make it strong enough to withstand abrasion, and render the rail sufficiently stiff, and capable fully of sustaining the action of the driving-wheels of the locomotive engine. Hitherto the established breadth seemed to have been about two and a half inches on the top web, or button, and Mr. Vignoles thought, from experience, that that breadth should be considered the *minimum*; however, the strength of this bearing part of the rail, being as the breadth and square of the depth, a greater breadth than absolutely necessary to prevent the tire of the wheels being grooved, would add to the weight of the rail, without increasing the strength more than in the direct ratio of the breadth, whilst the same quantity of material, disposed in terms of the depth, increases the strength in the duplicate ratio. Considering the great increase of weight in the locomotive engine of late years, and the continued wear and tear on the rail, from the action of the driving-wheels, and looking to the state of the iron of the upper works of those railways which have not very heavy bearing surfaces, it would seem that, while two and a half inches is a *minimum* of breadth, the chief attention is now required to the proper depth, to resist abrasion and exfoliation which takes place, especially if the iron is not perfectly well rolled. Railway bars are compounded of fagotted iron, and if the pieces are not properly welded the bearing edge is broken down, and peels off; but, supposing the iron good, and the manufacture perfect, the heavy effects of the engine must be provided against, and experience shows that an inch and a half is not too much for the depth of the top web, or bearing part of the rail, and two and a half inches being the breadth, then three and three-quarters—or, say four square inches—should constitute the sectional area of the part that is exposed in receiving the direct action of the driving-wheels; this is the section actually requisite, and the greatest additional strength being to be obtained by in-

* See Journal, No. 1, Vol. I.

creasing the depth, if possible, this is the point to be attended to. It thus appears that a weight of 36 lb. per yard is required to sustain the engine, and all beyond will belong to the mode of attaching the rail to the support below.

In treating of the wear and tear of rails, Mr. Nicholas Wood has given some curious and interesting results of experience; but the weight of the locomotive engines used is stated to have been only 10 tons, and of this the weight on the driving-wheels would probably not exceed six or seven tons. The result of a variety of experiments on the malleable iron rails of the Stockton and Darlington Railway gave one-tenth of a pound per yard as the absolute amount of fair abrasion; some statements, however, made it much higher, being one-sixth of a pound. On the Killingworth Colliery it was one-eighth of a pound. On the Liverpool and Manchester Railway, some years ago, three rails were taken up, carefully cleaned and weighed, relaid, and taken up again at the end of one, and again at the end of two years: the wear was found constant, and about one-tenth of a pound per yard per annum. If we were to take this to be the true wear, and suppose it to arise wholly on the upper surface of the rail, the result would be but the 84th part of an inch in depth, and it might be supposed to take 100 years to wear away a rail from mere abrasion. But later experience shows that the increased weight of engines acts very destructively on rails whose upper webs are not sufficiently strong, and of the best manufacture. We may take 10 tons as the present average weight on the driving-wheels of a locomotive engine; and, if this is to be effectually provided for, the button, or bearing part of the rail, must not be less than 40 lb. to the yard. Now the form of the remaining part of the rail will depend upon the manner in which it is to be fastened down to the support below, either by being fixed in a chair, which is itself to be again fastened to something else, or by being screwed down, as the rails on the Great Western, Croydon, and the new part of the Greenwich Railway; or, finally, secured in the simple manner described in the last lecture. A comparatively very small addition to the theoretical form of rail to be sustained in a chair, gives a section which has the advantage of being capable of being turned in either direction, or vertical position, and hence the top and bottom of the rails have, of late, as previously stated, been made equal and similar, connected by a neck of proportionate dimensions. With the present heavy rails, of nearly 80 lb. to the yard, the average weight of the chairs, including the joint chairs, may be taken at 20 lb. per yard, reducing the intervals of support to that constant distance. Thus, we have an aggregate of nearly 100 lb. weight of iron per yard of each single rail. If, then, we could in any way get rid of the extra weight required to fasten the rail into the chair, and dispense with the chair altogether, it seemed to Mr. Vignoles to be desirable to do so, provided the object in view was equally well attained; and he contended that such would be the case with a 50 lb. rail attached, in the mode before described, to a longitudinal bearing of timber; for the whole strength of the upper or bearing part would be retained, that being as the breadth and the square of the depth; thus, with a weight of iron just one-half, would be equally efficacious, and it only remained to compare the supports in either case. Now, as stone blocks seemed to be discarded by universal consent, the question of the supports below is narrowed to that of *transverse* or of *longitudinal* wood sleepers. Sufficient experience had been obtained to warrant the conclusion that, for the purposes of this argument, the cost of fastening and of laying the rails, ballasting, drains, &c., taken as a whole, were nearly the same for both systems, and it only remained to contrast the quantities of timber, and, always considering a locomotive line to be the one to be made, it may be stated that this cubing was about double for the longitudinal system to that in the transverse method of laying the sleepers. In short, looking at first cost only, there was a saving of 100 lb. of iron, and an increase of two cubic feet of timber in each yard of single trackway of the former over the latter mode, so that strictly the longitudinal system was the cheapest; but to avoid minor objections, let the cost of each be taken to be the same, which was giving a decided concession in favour of the transverse system. But this was a very narrow view to take of the question, which wholly omitted the economical results from diminished wear and tear of the engines, of the railway, and of the carriages, as had been most especially exemplified on the Dublin and Kingstown Railway, where the massy granite blocks originally laid down had been all replaced by longitudinal sleepers, and though the old light 45 lb. rails and 15 lb. chairs were retained, the diminution of the annual maintenance was most remarkable, though there was not a railway in the United Kingdom where so many passengers were carried daily throughout the year.

The expense of keeping up the double way, now that the system of longitudinal timbers has been quite carried out, is less than one-third of the corresponding expense per mile per annum of maintaining the London and Birmingham Railway. Mr. Vignoles then read a variety of tabular results of the cost of the three various systems, going through all the details, and pointing out the exact measures and quantities, and stating the actual expenditure on the upper works of various lines of railway. The result seemed bed of the road was duly prepared, including all the items under that

that, for a double line of railway—upper-works, properly laid after the head, which were enumerated in a former lecture, and calculating, for the present heavy and powerful locomotive engine, that no less a sum than £5000, and, in most cases, £6000, per mile was necessary, and that, in many instances, it had reached nearly £7000—the market price of iron and timber, also the quality of the latter, the greater or less facility of obtaining materials for ballast, &c., affecting the amount, and these large sums were independent of the earthwork, masonry, land, fencing, management, stations, carrying establishment, &c. Mr. Vignoles also gave a number of drawings and diagrams contrasting the three systems, and exhibiting, in a very explanatory manner, the modes of laying and fastening. He also exhibited the rail, chair, and fastenings, for the transverse method, with all the recent improvements introduced by Mr. Cubitt on the South-Eastern Railway, and as manufactured by Messrs. May, of Ipswich, and then produced the rail with the dove-tailed slot, and the mode of attachment to longitudinal half baulks of timber, repeatedly alluded to in this and the preceding lecture, observing forcibly, that, if the same effective results were obtainable by the latter simple method as by the former complicated one, it was not only to be preferred in this kingdom, but was peculiarly eligible for such countries as Russia, Poland, Germany, in general, France, and America, where wood is usually in great abundance, and where iron is comparatively scarce, especially in the form required for railway bars, and, of course, the prices became in proportion. Mr. Vignoles quoted largely from the works and reports of Tredgold, Barlow, and Lecomte, and stated a number of mathematical and empirical rules laid down by those authors, which, he stated, were chiefly relating to rails supported at intervals, but, though he felt it right to lay them before the class, he considered that farther experiments and investigations were requisite, and particularly in reference to the perfect combination in one support of the iron and timber in the longitudinal system, as explained and advocated by him, of which the Professor insisted, the great advantage and peculiarity was that of obtaining a perfect fastening, independent of the fibre of the wood, or the tenacity of the screws or bolts therein, and of obviating the hitherto well-founded objections to the mode of attaching rails having a continuous bearing, which had not been able to prevent a vertical play of the iron on the timber.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

TWELFTH MEETING, 1842.—Held at Manchester.

(Continued from page 277.)

REPORT ON EXPERIMENTS ON THE TRANSVERSE STRENGTH OF HOT AND COLD BLAST IRON. By Mr. Fairbairn.

THE bars, as described in the former reports, were supported by standards, 4 ft. 6 in. apart, and were loaded with different weights; they were occasionally carefully examined, and showed a very slight progressive deflection. He had no doubt that they would ultimately break, but the progress was very slow. He read a table showing the weights laid on, and the deflections of each bar.—Mr. Hartopp said, that Mr. Fairbairn's former experiments on hot and cold blast iron had created a false impression with regard to the strength of hot blast iron. Mr. Fairbairn had found very little difference between the hot and cold blast; but his experiments, made with great accuracy, and in which the weights were laid on with great care, were of little practical advantage, as these were not the circumstances under which iron was tested in practice: there percussion, violent and sudden impact, should be expected, and here lay the great deficiency of hot blast iron. Even in Mr. Fairbairn's experiments, Oldberry No. 2, cold blast, bore twice the percussion of Oldberry hot blast; and Milton hot blast was only half the strength of Elsicar cold blast, made of the same ore and smelted with the same coal. Experiments had been made in Yorkshire with great care; the results being, Low Moor cold blast bar iron, 3 in. diameter, broke with 6 blows, ditto Scrap, 3 blows, ditto hot blast, 1 blow; again, Low Moor cold blast 18 blows, Bierly ditto, 18, hot blast of as good materials, 3 blows; again, Elsicar cold blast, 21 blows, Milton hot blast, 1½ blow; therefore, in iron for axles this difference of at least five-sixths of the strength was very important. As to scrap iron, it bore too high a character. Scrap, made on the old plan, was all charcoal iron, but the modern scrap iron was very inferior, being 32s. 6d. per ton cheaper, so that ironmasters put off as much of this cheap material as possible. Hot blast iron was rejected now for water-pipes, &c., and even for cannon balls; and, in fine, he had been told by very eminent marine engine makers, that where any percussion took place, hot blast cast iron was only half the strength, and wrought iron only one-sixth the strength of cold blast.

Mr. Fairbairn explained, that he had found great difficulty in obtaining specimens from the different iron-masters, who would of course send, when

possible, the best specimens, but every care had been taken to insure accuracy in the experiments.

Mr. Hodgkinson said that the average strength of hot blast had been $\frac{1}{10}$ weaker than the cold, but the inferiority was chiefly in the softer irons; as the hardness increased, the two kinds approached to equality, and in the hardest irons the hot blast was the best. He thought his experiments, made without any interest on either side, and with the greatest care, were more to be depended on than experiments made by those who had an interest in the result.

Professor Vignoles explained, that the question of hot and cold blast had nothing to do with the late contract for cannon balls.

ON THE FORM OF SHIPS.

Mr. Scott Russell laid on the table the *Report of a Committee on the Form of Ships*. It contained upwards of 20,000 observations, the result of careful experiments on the resistance to models of ships of more than a hundred different forms and sizes, and extending from small models of 30 in. long, to vessels of 25 ft., 60 ft., and 200 ft. long, and above 1000 tons burden. These experiments were under the general superintendence of a Committee of the Association, consisting originally of Sir John Robison, Mr. Scott Russell, and Mr. Smith. Unfortunately, the ill health of Mr. Smith's family had altogether deprived the committee of his advice and assistance, but the observations were personally conducted by Mr. Scott Russell, who had to acknowledge the pleasure he had derived from conferring with his friend Sir John Robison, with whom he had frequent occasion to consult during the progress of the observations. The smaller experiments had been made in a reservoir in the ground attached to his (Mr. Russell's) residence, and the larger ones in the open sea. It was probable that these results, maturely digested, and illustrated by accurate drafts of the forms of the ships subjected to experiment, would be published in such completeness as might be practically serviceable to the naval constructor and mercantile ship-builder; and he would, therefore, confine the present report to a general account of the objects contemplated in the experiments, and the method by which these designs had been carried out. Several series of experiments have already been made, both by scientific bodies, and by public-spirited men, for the advancement of naval architecture. These had cost large sums of money, and consumed much valuable time and talent. To most of them it had been objected—unhappily not without reason—first, that they had not been conducted with an adequate knowledge of the wants of the constructor; secondly, that the forms of bodies submitted to experiment were by no means such as are used by the ship-builder; thirdly, that the scale on which these bodies were constructed was too small to claim for the results, as applied on a large scale, any considerable degree of confidence; fourthly, that it had not been established by what law the results of experiments on one scale of magnitude are to be transferred to a different scale, either greater or less; and, fifthly, that the apparatus formerly used was liable to errors which it was difficult to eliminate from the results. To obviate such objections was one great object in these experiments. Mr. Russell had contrived a new apparatus, which was so simple and convenient, that a uniform propelling force was obtained, by which vessels of any magnitude might be drawn by a uniform mechanical force along any given distance. The forms of the models employed were not confined to mathematical and arbitrary solids, but were those of such classes of ships as are either actually employed in navigation, or have been proposed for that purpose. Among these were some of the highest reputation. It was found that there were other circumstances besides the form of the vessel which affected the result; and that the form and dimensions of the channel were as important as those of the vessel in determining it. Experiments had been instituted on the largest as well as the smallest scale, to show the law of relation between different scales. These various modes of experiment were illustrated by reference to drawings and tables which were prepared for publication. As an illustration of the value of giving a proper form to ships, altogether independently of proportion or dimension, the following remarkable experiments were adduced:—Four vessels, of about 25 ft. length, having all the same dimensions of breadth and depth, of the same capacity and weight, and of the same draught of water, were towed together at the same time, under the same circumstances, and at the same velocity. Some writers on naval architecture have asserted that, in such circumstances, vessels would have precisely the same resistance. The forms of these four vessels were not, to an inexperienced eye, very dissimilar: they were all good sea boats, and each of them found its admirers to give it shape a preference over the others. These vessels, alike in all their principal dimensions, and weight, and area of midship section, and draught of water, differed so much in resistance, that the one had nearly double resistance to another: thus, at $7\frac{1}{2}$ miles an hour, the resistances were as follows:—

No. I. form	56.6 lb. resistance.
No. II.	138.5 "
No. III.	102.7 "
No. IV.	90.2 "

All of these were good sea boats, and it was one of the most valuable of these results, that No. I., the form of least resistance, was found also the best sea boat, the easiest, and the driest. The whole of the observations, comprising more than 20,000, were in the course of preparation for publication, so that the whole body of the observations would be at the disposal of the Members of the Association. It had been the aim of the Committee

to reduce the whole into the form most immediately conducive to the purposes of the naval constructor and mercantile ship-builder, and the drawings had been made on the scale and with the accuracy of the draughts of ships of the largest class.

Sir John Robison felt it his duty to state to the section, that although he had cordially given Mr. Scott Russell his co-operation in forwarding these experiments, and although Mr. Russell had made frequent use of the plural pronoun, yet that the whole of the merit, both of contriving and designing, and carrying out the system of experiment, was due exclusively to Mr. Russell.

Mr. Russell also explained a model showing the waves in a channel arising from the natural channel wave, and the wave resulting from the form of the boat.

Mr. Williams wished to know how Mr. Russell tested the horse power in the two boats which he had mentioned, as nominal power was not a fair test; and also whether he had paid attention to the difference in draught after the engines had been put in, the settling at stern or stem, &c., as the putting in the engine might make the vessel which had been slowest, when towed, fastest when driven by her own power—a vessel quick in slow water might be slow in a rapid current—in fact, every vessel had its own characteristic, and, therefore, many circumstances entered into the comparison between two vessels.—Mr. Russell said, that a reference to the report would show the steps which had been taken to insure accuracy. Of course in making experiments he had attended to all the circumstances which could introduce inaccuracy. In answer to Mr. Williams, he would say, that when the vessels were towed, the engines, stores, coals, &c. were exactly the same as when the engines were working; in fact, they had merely detached the tow rope and started the engines, and it so happened that the vessel which had been fastest in towing was also fastest in sailing with her own engines working, but he did not consider this as affecting the question.

Prof. Vignoles exhibited some specimens of newly invented carpet tapestry. He explained that these works were made on the principle of the ancient mosaics, being composed of innumerable transverse sections of woollen threads. No painting, no colouring was used; all the effect was produced by ends of worsted about $\frac{1}{4}$ of an inch long standing vertically, one end being seen, and the other cemented by India rubber to a cloth. The exact operation was yet a secret, but he believed that two frames of fine wire or perforated zinc (some with even 4000 perforations in an inch) were placed over each other exactly vertically, the distance being only regulated by the height of the room, in the present instance he believed about five feet. The picture to be copied being then traced on the top side of the upper frame, a workman passed threads of dyed wool through the corresponding holes in the top and bottom frames, of course, as in tapestry, varying his shades and colours until he is satisfied with the effect; this he can judge of by looking down on the upper ends of the threads, although to a person looking at the space between the frames, there seems only a confused and compact mass of worsted. When the workman is satisfied, the upper ends of the threads are covered with India rubber cement, and a cloth is laid upon them also covered with cement; the ends of the threads firmly adhere to this cloth. By means of a sharp cutting instrument, the entire mass of threads is now cut through transversely at about $\frac{1}{4}$ of an inch from the cloth, and this process being repeated, a fresh copy is obtained from every $\frac{1}{4}$ of an inch: in the present frames, being five feet apart, 480 copies can be cut, and as there is no limit to the distance, except the height of the apartment, thousands of copies may be taken of each. Were this not the case, the invention, however ingenious, would be too expensive to be purchased except in solitary instances as specimens of curious art: but, from the facility of reproduction, this fabric was likely to come into general use for carpets, rugs, curtains, table and chair covers, &c.; for carpets and rugs it could be made with a longer nap, so as to give any degree of substance.

A DESCRIPTION OF THE THAMES TUNNEL. By Sir M. I. Brunel, F.R.S.

Sir M. I. Brunel exhibited a diagram of the exterior elevation of the Thames tunnel, and also a representation of the machinery by which he supported its roof and sides during the process of excavation. He said he had no paper to read, and that his work would be very short; for, although it might be very difficult to describe a work that was to be accomplished, there was little difficulty in speaking of that which had been completed. All he had to say was simply to point to the representation, and say, that the tunnel which he had erected was like that. The tunnel was about a quarter of a mile in length, and was made under the river Thames. The difficulties were very great, and deemed insurmountable by many learned and scientific men. Indeed, the difficulties were much greater than what he himself had at first conceived them to be; for the ground to be excavated was quite different from that which had been brought up with an augur in the preliminary examination of it. However, he was determined to persevere; and, notwithstanding the many obstacles that from time to time presented themselves, he never considered the undertaking impracticable. Sir M. I. Brunel then directed attention to the apparatus he had devised for sustaining the arch during the progress of the works. It was upwards of 60 ft. wide, by 22 ft. high, divided into 12 compartments, each containing three arches, one above another. The top was horizontal. Each compart-

ment could be moved forward or backward at pleasure, so that, as the workmen excavated a few inches, the superincumbent pressure was immediately sustained by the protrusion of that part of the machinery opposite which the excavation was made. The ground was cleared away in front of each alternate division of the moveable arches, so that six were always stationary, sustaining the roof of the tunnel; while the other six were employed in making additional progress. Some of the strata overhead was quite dense, while part of it was in a fluid state. The workmen never advanced more than six inches at a time, and then the props were immediately introduced into the vacant place, and the building-up of buttresses and arches followed in the rear. During the progress of this extraordinary undertaking, five eruptions of the river had taken place. One of these occurred when the tunnel had been half done. This was in consequence of the men having struck for an advance of wages; and, during the delay which was thus occasioned, a very large hole opened in the top, and the water came pouring in. When this occurred, said Sir Mark, every one made a hole for his stopper; but he could get no one to make a stopper for the hole. By that unfortunate eruption, five men were lost. However, he succeeded in stopping the leakage, and in pushing forward the works, until he reached the other side of the river. After surmounting many difficulties, he had now the pleasure to come before the public for the first time, and say the work was done. Many had endeavoured to discourage him, and thwart the undertaking, but the Government were always exceedingly liberal; and the Duke of Wellington, from the first moment that he had seen the plan, conceived a high opinion of its practicability, and forwarded the undertaking as much as possible. A tower, 290 ft. in diameter, was erected at each side of the tunnel, and carriages could be admitted through them with the greatest ease. In answer to a question from Mr. Roberts, Sir M. I. Brunel said, that the quantity of water percolating at present through the tunnel was about 60 or 70 gallons per minute. About six weeks ago, 480 gallons oozed through; the quantity had since been reduced to about 60 or 70; and, in a short time, it would be reduced to nothing.

ON THE IMPROVEMENT OF THE SPECULA OF TELESCOPES. By Mr. Fox Talbot.

The subject occurred to him about two years ago, when the Earl of Rosse (then Lord Oxmantown) was making much larger specula for reflecting telescopes, than had ever been obtained before; and he thought, if once we had a very large and perfect speculum, it might be possible to multiply copies of it by means of the electrotype—by galvanic means taking an electrotype cast from the existing original at a small expense—which, if not quite so perfect as the original, should be at least very fine and important instruments. He had observed, that if an electrotype cast were taken from a perfectly polished surface, the cast was also perfectly polished; so that no defect of form from this cause could have an injurious effect on the speculum. The great and obvious defect was, that electrotypes being in copper, which reflected but little light, a very large speculum of copper would not reflect more light than a very small one in speculum metal. He mentioned these ideas to Professor Wheatstone, who said the same had occurred to him, and he showed him a paper which he had drawn up some few months before, and which he lent him.

Mr. Talbot read this paper of Professor Wheatstone's, in which he suggested the taking galvano-plastic casts of specula in platina, palladium, silver, or nickel, and for especial purposes gilding the copper; taking care that the two precipitations adhered well to each other. He suggested that voltaic electricity might thus enable us to copy large specula (like those of Lord Oxmantown), at a slight expense. So that (said Mr. Talbot) the idea had suggested itself independently to both of them; but on comparing notes they found differences. Though it had occurred to him (Mr. Talbot) to precipitate white metals, yet he did not think that platina would have a sufficiently beautiful white metallic polish. Silver he rejected, because easily oxidized by the atmosphere. Nickel he had not tried, but it appeared likely to answer. Professor Wheatstone had, however, made choice of platina, and varying the quantity till he found the required proportion, he obtained a mirror in platina which appeared to him (Mr. Talbot) to have quite brilliant polish enough, and to be white enough to answer the purpose; and he considered, therefore, that Professor Wheatstone had proved that, at least in one form, the specula of telescopes might be made by voltaic precipitation. His own idea was, that it might be possible to whiten the surface of the copper without injuring the form; and, therefore, having obtained a speculum in very bright polished copper, he exposed it to the vapour of the hydro-sulphuret of ammonia, which had the property of turning copper white; and it did so without, so far as he knew, in the least injuring the form of the metal. A copper speculum was subject two evils; it reflected but little light, and it became easily tarnished; but, when whitened by exposure to the hydro-sulphuret of ammonia, the surface was transformed into a sulphuret of copper, and not only was a white metal obtained, but it was no longer subject to be tarnished by the atmosphere, the sulphuret of copper being a stronger chemical compound than the oxide of copper, and, consequently, oxygen had no more effect upon it than on platina. Having obtained a copper cast from a polished speculum, he, (Mr. Talbot) whitened it, and transformed it into sulphuret of copper; and, after having retained it about a year, he did not perceive the smallest alteration in any respect.

This, therefore, appeared to him a mode by which such important results for astronomers could be obtained. For the last year, perhaps, nothing farther had been done, either by Professor Wheatstone or himself; but the other day, being at Munich, he (Mr. Talbot) visited Professor Steinheil, who showed him his inventions, and told him he had invented a method of making specula by the electrotype. It so happened, that both Professor Steinheil and himself had published their respective methods about a month or six weeks before, the Professor having read a communication on the subject before the Academy of Sciences at Munich, and printed it, and he (Mr. Talbot) having published his in England. Their modes were, however, different, as Professor Steinheil precipitated gold upon the speculum of copper; and, having precipitated a certain thickness of gold, he then precipitated copper on the back of the gold, to give it sufficient thickness. He (Mr. Talbot) should have thought beforehand that gold would not reflect light enough to be available; but Professor Steinheil informed him he had found, by careful experiment, that it reflected more light than polished steel. He allowed Mr. Talbot to look through a Gregorian reflecting telescope, of which the speculum was a common one, but gilded, and he found the image perfectly clear and well-defined. A slight tinge of yellow was thrown over all the objects, but the image was perfectly clear and defined. Now it was evident, that if the form of the speculum was not destroyed by gilding it, much less would it be altered if formed originally of gold. If a film of gold were precipitated upon a speculum of copper, we must, to a certain extent, alter its figure; but that alteration must be very small, because there was no perceptible defect in the image. Professor Steinheil said, that the astronomers of Germany were much pleased with his plan, and were greatly engaged in the subject; and that in the course of a year he should have a very large telescope, furnished not only with a speculum, but also with other apparatus, voltaically formed, so that telescopes might be made all from a good model, so as to insure greater accuracy of proportions; and in this way even very large telescopes might be constructed at a comparatively trifling expense. With reference to the precipitating copper on the back of the gold, the Professor had a simple expedient for securing adhesion. He first precipitated gold from the cyanide of gold, and he mixed with it cyanide of copper, and kept gradually increasing the quantity of the latter sort; so that an alloy was precipitated which was continually increasing the copper with respect to the gold, till he had a speculum whose surface was gold, and which then became an alloy, the quality decreasing, till, at the bottom, it became pure copper. This was important, because, without such experiments, one would not have known that such results would have followed; for some philosophers supposed that, if we attempt to precipitate the salts of two metals, only one was precipitated; but Professor Steinheil informed him that they precipitated in union. He thus obtained a speculum with a face of gold and a back of copper. But, supposing the largest, cheapest, and best speculum were obtained, the framework of the telescope would be so gigantic, that few observers would be able to use the instrument. With a focal length of 60 to 80 ft., it would be quite unmanageable for any private individual. The idea occurred to him (Mr. Talbot) to have a tube fixed in an invariable position, and to have a perfectly true plane mirror, of a size somewhat larger than the concave speculum, placed in front of the tube, with an aperture in the centre. This plane reflector should be moveable about its centre in any direction; so that luminous bodies, falling first upon the plane reflector, were then reflected against the concave reflector, and passed through the aperture. The only motion requisite for the plane mirror would be one about its centre. The mechanical difficulties in the way of this plan would be far less than in the common method. Professor Steinheil's idea on this point was somewhat different. He (Mr. Talbot) did not think it important in what direction the tube of the telescope was directed. Professor Steinheil's idea was, that it should be pointed directly to the pole of the heavens, and kept as steady as possible, and that the plane mirror should have a simple motion of revolution, indeed two motions, but about a rectangular centre.

Remarks.—Sir William Hamilton expressed his pleasure at hearing this communication, and said, the want of some such contrivance as the last had become sensible to those having great command of money and power. The Earl of Rosse had lately cast a metal speculum, weighing several tons, and six feet in diameter, which his lordship intended should be moveable only in or very near the meridian, on account of the great mechanical difficulty of moving so great a mass, so as to direct it at pleasure to every point of the heavens. The advantages, therefore, would be great from carrying out the plan last mentioned. It was clear, that its success and utility must depend greatly on the excellence of the original. Lord Rosse had, hitherto, been unrivalled for making specula on a large scale, and for his means of carrying forward this magnification of the mirror to an unparalleled extent; and perhaps the degree of acquaintance with which that nobleman had honoured him, and the recollection of what Dr. Robinson had recently said in his lordship's name, warranted him (Sir William) in saying, that Lord Rosse was disposed to give every facility to persons of science, desirous to make use of his instruments.

Mr. Isaac Holden said, the late Earl of Stanhope had invented and erected a telescope on the plan (as to the fixity of the frame-work) which Mr. Talbot recommended. The instrument was stationary, and he could sit still and view more than one-half the heavens, taking in even 20° behind his head, by means of an arrangement of mirrors.

Sir D. Brewster mentioned a similar plan, proposed twenty years ago, by an American gentleman, to the Royal Society of Edinburgh. There the mirror was not vertical like Lord Stanhope's, but horizontal, consisting of a dish

of metal in which a quantity of mercury was placed, and a rotatory motion was given to the disc, so that the mirror assumed a concave form, giving a parabolic surface, of the actual form required to reflect bodies; by which means a mirror was constructed in one instant of time. This appeared so impracticable to that society, that they did not venture to give any account of it in their memoirs.

PHOTOGRAPHIC DISCOVERIES.

Sir David Brewster said, he was requested to communicate an account of some remarkable facts connected with the theory of photography. A new process of producing photographic impressions had been discovered by Dr. Moser, of Königsberg; and an account of the discovery had been brought to this country by Professor Bessel, who received it from the discoverer himself. The subject was most important, and it would have been a great misfortune if the physical section had left without having been made acquainted with it. The following were the general facts connected with it:—A black plate of horn, or agate, is placed below a polished surface of silver, at the distance of one-twentieth of an inch, and remains there for ten minutes. The surface of the silver receives an impression of the figures, writing, or crest, which may be cut upon the agate, or horn. The figures, &c. do not appear on the silver at the expiration of the ten minutes, but are rendered visible by exposing the silver plate to vapour, either of amber, water, mercury, or any other fluid. He (Sir David Brewster) had heard Professor Bessel say, that the vapours of different fluids were analogous to the different coloured rays of the spectrum; that the different fluids had different effects, corresponding to those of the spectrum; and that they could, in consequence of such correspondence, produce a red, blue, or violet colour. The image of the *cameo obscure* might be projected on any surface—glass, silver, or the smooth leather cover of the book—without any previous preparation; and the effects would be the same as those produced on a silver plate covered with iodine. Professor Bessel did not pretend that this discovery was perfect. He also mentioned what was far more important than all this, in a scientific point of view—that Professor Moser had discovered the existence of latent light—of light residing in bodies, and exhibiting its action after having lain in those bodies for we know not how many years. If it were an actual physical fact that latent light did exist—if light took its residence permanently in a body—if, having motion, it stood still, and did not shine—if it did not trouble the ether in any way, was its motion extinguished? and, if so, how was it to be put in motion again? This idea of latent light corresponded with Newton's opinion, that light entered the surface of charcoal, and never was brought out again; but Moser had discovered a mode of bringing it out again.

Sir William Hamilton: "Have you any account that he has discovered the fact?"—Sir David Brewster: "He conceives he can prove the existence of latent light."

Professor Bessel said, he scarcely had time to obtain from Professor Moser all the particulars of his discovery; but he (Professor Bessel) had seen a plate of silver representing the image on a black agate cameo. This photographic image was very good, and looked as well as any of those likenesses taken by Talbot or Daguerre. Professor Moser said he had produced those likenesses even at midnight, without using any light. The exclusion of light made no difference whatever in the phenomena.

Sir David Brewster thought the image thus produced might have been as perfect probably as the first specimens of daguerreotype. He had alluded to charcoal absorbing the rays of light—there was another analogous phenomenon; if a tube were filled with nitrous acid gas, and rays of light passed through it by a lens, the fluid would almost lose its yellow colour, and become so white, that every object might be seen through it; but if it were exposed to a higher temperature, it became gradually yellow, then orange, and at length it would become of such a deep red colour, that the light of the meridian sun could not pass through it—the gaseous body standing like a column of charcoal before the spectator. By allowing the gas to cool down, it gradually becomes transparent, passing backward through the same steps. The opacity arises from the heat; and, if there be such a thing as latent light, it must have acted on the particles of the gas.

On the Pressure of Earth against Walls. By C. W. Buck, C. E.

Mr. Buck thought it desirable to investigate the resistance offered by earth to displacement, when a rigid vertical plane is thrust against it—as where abutments of bridges are made, for economy, to depend for stability on the resistance of the earth behind them. In cases of this sort, the tendency of the pressure is manifestly to cause a rupture of the earth, and force a wedge of it upwards; and it is curious to observe that the angle at which this rupture takes place (the angle of least resistance) is the same as that given for the maximum thrust by Poncelet—that is, half the complement of the angle of repose. To estimate the horizontal thrust against the wall below the spring of the arch, when this arch is sprung from the top of the wall, and when the entire height behind the wall is filled up with earth to the level of the top of the roof of the arch, there are two masses of earth to be considered:—1st. The wedge of earth acting against that portion from the top of the wall up to the top of the arch; and, 2nd, The quadrilateral figure left when this wedge was subtracted from the entire wedge from the

foot of the wall to the top. It is the horizontal thrust of this latter position which is to be considered; and this horizontal thrust is equal to the horizontal thrust of the entire wedge minus the horizontal thrust of the wedge above the top of the wall minus the friction of the base or line of rupture of this latter wedge. This can be found easily for any particular case; but it is also desirable to find the proper height from which to spring the arch, so that the friction of the lines of rupture of the two wedges shall neutralize the horizontal thrust against the wall below the arch. This is found to be when the distance from the level of the roof of the arch to the top of the wall is equal to the entire depth, from the top of arch to the foot of wall, multiplied by the square root of the tangent of angle of maximum thrust. Following out this result for fluids, where the friction is nothing, the arch should spring from the bottom of the wall; and this Mr. Buck called the "Tunnelling Equation," because it shows what thickness of roof is sufficient to neutralize the pressure of the sides, and points out how far it is necessary to cut the ground open, curb it, and cover it again when there is not sufficient thickness of roof for ordinary tunnelling. It shows, also, how strong to make the side walls, and what form to give them to resist the lateral thrust. The investigation further proved the danger of the common practice in sinking shafts, of sinking to a considerable depth before curbing, or securing with brick-work, from the supposition that the earth must needs stand of itself; and, therefore, that it will answer as well to begin the curbing at some inferior point; whereas the reverse is true—that if the top be well secured, the part below will not move. These remarks, however, are based on the supposition that the earth is homogeneous. Mr. Buck was proceeding to read over the mathematical formulæ of his investigation, when—

The President thought the subject was too analytical to be interesting to the Section.—Professor Moseley stated that Poncelet had lately investigated all the conditions of subjects taken up in Mr. Buck's paper, and given formulæ and tables for their application, by practical men, except the one for tunnelling. Poncelet's paper was published in the *Memoirs of the Academy*.

Sir Mark J. Brunel thought it dangerous for engineers to place reliance upon formulæ which applied only to homogeneous ground. In the Thames Tunnel he had found ten or twelve different strata in a depth of eight feet; and, from the constant fluctuation of the weight above, and the fluid portion of some part of the ground, theoretical inquiries would have been useless in determining the manner of his proceeding.—Mr. Buck observed, in answer, that even in the case of fluid ground, theory assisted in determining the resistance necessary. Taking the London clay as an example, the friction in the line of maximum thrust was $\frac{1}{10}$ of the weight; and by comparing the specific gravity of this clay with water, he found that where, by the infiltration of water, this friction was reduced to $\frac{1}{20}$, the pressure was equal to hydraulic pressure, and when the friction was reduced to 0, it was double hydraulic pressure.

Sir John Robison made a short communication on the subject of a mode of making tessellated tiles and other objects by the compression of dry powder of clay, by Messrs. Minton & Co., of Stoke-upon-Trent. Sir John stated, that the advantages of the invention were the perfect truth of the tiles. When formed of wet clay, they almost invariably warped and became crooked. In this invention, a mould was filled with the dry powdered clay, which was subjected to heavy pressure, which caused it to cohere sufficiently to bear being placed in the kiln, where it was burned in the usual manner. Some specimens of tessellated tiles, and also of roofing tiles of a new construction, much lighter than ordinary tiles, and by which the capillary action of water, under the edges of the tiles, was prevented, were exhibited. The tiles were exceedingly accurate in point of form, and appeared extremely well adapted for the purposes for which they were intended.

Mr. Brockedon exhibited specimens of his *patent India rubber stoppers for bottles*, explaining the late improvements in the construction of the cores on which the India rubber is spread. The present cores, he said, were made of cotton twisted into strands, &c., by means of a machine, which he explained by a diagram, the cylindrical rope now consisted of several strands of tightly twisted cotton, lapped with flax thread, and laid together longitudinally, loose fine cotton rovings being placed between them; the entire was then lapped in a cylindrical form with flax thread, attaining by this method the advantages of perfect roundness and firmness; they also gave sufficient hold to the corkscrew, and bore the heating process well. These stoppers would slide on glass when wet, but not when dry, (although there was no cohesion in this latter state,) so that the bottler, by slightly wetting these stoppers with the liquor which he was bottling, could easily insert them; and when this slight film of moisture was dried up, the stopper required considerable force to withdraw it.

Mr. Louis Schwabe made a short communication on the formation of artificial threads of glass, for the manufacture of ornamental damasks, some very beautiful samples of which he exhibited to the section. Mr. Schwabe stated, that he had tried various kinds of glass, and found that that which was best adapted to the purpose was common window glass; the samples before the meeting having been made from the broken windows of his own establishment. There was one peculiarity in the matter which was worthy of remark, that the minute fibres of glass drawn from the lamp were always of the same shape as the bar of glass from which they were drawn. If that was round, the thread was round, if square or flat, the form of the thread varied accordingly; and, as a flat thread reflected the light better, and con-

sequently appeared more lustrous than a round one, the best form was a narrow flat slip, such as window glass readily produced. Mr. Schwabe showed the apparatus used, and the process adopted in spinning the exceedingly minute threads, of which from one to two hundred were used to form a single shoot of the web. He also showed the mode in which the weaving was performed, which was extremely simple. Mr. Schwabe said that he did not make this communication on account of any novelty in the use of glass, but in the hope of drawing attention to the many new materials which might be used in the manufacture of textile fabrics; and he produced also some samples of Manila flax, the fibre of the *pina* plant, from which a beautifully delicate and transparent cloth could be made. The specimens of manufacture thus produced, though not very perfect at present, seemed to promise more satisfactory results when matured by experience.

Mr. Hodgkinson explained *his apparatus for trying the strength of materials*. He brought his apparatus forward, as he had made many experiments; and he was desirous to render them as trustworthy as possible, by convincing the members that every care had been taken to ensure accuracy. Other experiments had been rendered unworthy of reliance, from injudicious methods of affixing testing apparatus—as those of Rennie and Captain Brown in iron; Girard's experiments, &c. In crushing specimens, it was necessary that both ends should be well bedded, and the pressure transmitted through the axis. To this, other experimenters had not always attended, and by using the pressure of bores directly on the substance to be crushed, they introduced the different errors arising from the pressure being oblique, transmitted through the side, or being exerted on mere points, instead of equally exerting its force over the entire top surface: to obviate these objections, he had devised apparatus by which all these errors were avoided. Mr. Hodgkinson explained the crushing apparatus by drawings, &c. In experiments on tearing asunder, he had also taken great care, by means of apparatus, which he exhibited and explained, that the strain should be through the axis, and otherwise free from causes of error. Mr. Hodgkinson explained his experiments on torsion, and illustrated his observations throughout by many models and specimens of the substances on which the experiments had been made.

Professor Moseley asked whether, in the experiments on beams, care had been taken to obviate the effects of the friction of the beams on the supports, as this would effect the direction of pressure, altering it from vertical to inclined, and the neutral line only passed through the centre of gravity of the beam when the pressure was vertical; also, if care had been taken in laying on the weights, as a weight suddenly laid on produced mathematically twice the effect in deflection. Theoretically, the weight should be increased by small additions, even as grains of sand.

Mr. Hodgkinson said he had taken all precautions with regard to the weights; they were added by small portions, and with great care; the beams rested on tolerably smooth cast iron, on which he believed the friction would be of little importance.

INSTITUTION OF CIVIL ENGINEERS.

April 5.—The President in the Chair.

MENAI LIGHTHOUSE.

Description. By D. P. Hewett, Grad. Inst. C. E.

THE Menai Strait is peculiarly fitted for a harbour of refuge for vessels entering the rivers Dee and Mersey from the north, and the increasing number of ships frequenting this navigation, as well as the insufficiency of its beaconage, rendered it desirable that the entrance should be distinctly marked; the Corporation of the Trinity House accordingly decided, in 1834, to effect this object by the construction of a Lighthouse, to be situated on a sunken rock about 200 yards from the Anglesey coast on the west side of the entrance, which is divided by the Puffin Island into two channels, defined by a beacon and two buoys.

The principal novelty in the construction of the lighthouse is the base, which, instead of diminishing, like the Eddystone, with a regular curve, recedes by a series of rectangular offsets; the object of this form of structure is to break the force of an impinging wave, and prevent the whole effect of its shock being thrown upon the upper part of the building, as it is when guided up by the curved surface.

The building, which was designed by Messrs. Walker and Burges, is a handsome circular tower 75 ft. high, 40 ft. in diameter at the base, and 20 ft. 6 in. diameter at the top, terminated by a castellated parapet, and entirely constructed of Anglesey marble. The base of the building is solid to the height of 22 ft. 6 in. from the rock, diminishing at intervals of 2 ft. 3 in. by offsets of 9 in. each, up to 6 ft. 9 in. above high-water mark, where its diameter is 22 ft. On that level is the entrance doorway (which is accessible by steps cut in the base stones). The interior contains six floors, forming rooms for the uses of the light-keepers, stores, &c. Every precaution has been taken to render the exterior joints of the courses water-tight; each stone is secured to that below it by a sinter joggle, and two oak trenails, passing entirely through it, and entering 8 in. into the lower stone. On the upper bed of each course of stones is a projecting fillet, which fits into a corresponding groove in the under side of the course placed upon it, in order to prevent the water from being forced between the courses. The two upper

courses project internally and externally, to form a gallery which supports the parapet and the lantern, the foundation and the framing of which are of cast iron. The wall diminishes gradually in thickness from 6 ft. 9 in. to 2 ft. The communication describes minutely the construction of the floors, the partitions, the stairs, the lanterns, &c., and the proportions of the materials for the mortar, which consisted of three measures of sand, one of ground lime, and one of Italian pozzuolana.

The light is a stationary, red, dioptric light of the first order, without mirrors. The burner consists of four concentric wicks, of which the largest is 3½ in. diameter; its ordinary consumption of oil is one pint per hour. The various bearings are given from which the light is visible at sea. After deducting all expenses, the surplus revenue derived from the light dues, during the year 1840, is stated to have been £388 13s. 3d. The lighthouse is connected with the shore by a foot bridge, which consists of a platform 2 ft. 3 in. wide, supported upon a series of iron columns placed 10 ft. apart, secured into the rock, and strengthened by stays. This slight construction has withstood the violence of the waves for three years.

The paper notices the buildings which have been erected on the shore for the residence of the light-keepers, and then proceeds to describe the beacon before alluded to, which points out a dangerous ledge of rocks on the opposite side of the channel. It consists of a cone of masonry, 20 ft. in diameter at the base, and 37 ft. high, surmounted by a staff and globe rising 13 ft. above the apex of the cone. The globe, which is 4 ft. diameter, is formed of copper bands, and is 36 ft. above high-water mark.

The whole amount expended in these different constructions is stated to have been about £12,800. The communication was illustrated by a series of detailed drawings and a chart of the straits.

April 12.—The President in the Chair.

ON BREAKWATERS.

"Observations upon the Sections of Breakwaters as heretofore constructed, with suggestions as to modifications of their forms." By Lieut.-Col. H. D. Jones, R. E., Assoc. Inst. C. E.

This communication is the result of several years' observation of the effect of storms upon the sea faces of breakwaters and piers: those principally alluded to, and of which drawings were exhibited, were Plymouth, Kingstown, Howth, Ardglass, and Dunmore; a section was also given of the sea wall of the Kingstown Railway, and of the mole of St. Jean de Luz.

The mode of building with "Pierre perdue" appears to have been brought into notice about the time of Louis XV., when the cones at Cherbourg were sunk, and filled with stones as a foundation for a wall; since then the general method of constructing sea-defences has been to throw down masses of stone, allowing them to form their own angle, subject to the effect of the sea in giving them a greater or less slope. In many instances this rough foundation has been paved down to below the low-water mark with squared blocks of stone secured with much care, and above this a wall is built of solid masonry, generally with a considerable slope on the sea face. The author contends that the system of assimilating the sea face of breakwaters to the form of the shore at low water is erroneous, because the sea shore is the line of least or non-resistance, not opposing, but yielding to the sea. He asserts that, as far as he can ascertain, no pier or breakwater constructed with a sea slope has been found to resist the effects of storms without considerable repairs and expense being subsequently required. He then gives his observations upon the several sections, and states that the waves have the most violent effect at about half tide, hence the stones at that line are first disturbed, and then are carried down into the deep water. To parry this evil nearly 200,000 tons of stone have been deposited on the fore-shore of Kingstown Eastern Pier, yet more must still be added. Similar additions have been repeatedly made to Plymouth Breakwater, with no better effect. At Dunmore iron chains have been fixed in the face of the walls to secure them. At Howth a slope of 3 to 1 has been found insufficient. At Ardglass the pier head and lighthouse have been washed away. From these and numerous other examples, it is argued that piers in exposed situations with a considerable inclination of the sea face do not resist the violence of the waves, whereas there are many instances of upright walls having resisted perfectly. As instances of this, Old Dunleary Pier is adduced as being nearly perpendicular, yet never having been injured during a long series of years, although quite as much exposed as the New Pier, now called Kingstown; Kilrush Pier, although not built of heavy materials, has resisted all the shocks of the heavy seas which break upon it from the Atlantic.

From these considerations Colonel Jones proposes upon the "Pierre perdue" to rise a perpendicular wall from a little below the level of low-water spring tides: this form, he contends, would resist the upward pressure of the sea upon the broad bases of the stones, and prevent their being removed. He argues that although the proposed walls would require to be built with squared stones, instead of "Pierre perdue," that the cost would not be greater than at present, as the area of the section of his proposed wall if applied at Kingstown would be only 4860 square ft., whereas the sectional area of the present pier is 10,085 square ft. The French appear to have partially adopted this form at the new works at Cherbourg; but he considers this mode of construction objectionable, inasmuch as it leaves in front of the outer face that part of the breakwater which is most subjected to injury. An extensive

series of drawings, containing the plans and sections of existing breakwaters and piers, showing the injury sustained from storms, accompanied the same.

Colonel Jones explained by the various sections of breakwaters shown in the drawings, the changes of form, and the additions to their cubic content which had been made at different periods, in consequence of the violent action of storms.

The Plymouth Breakwater has had its form altered three times; each time the base has been extended, and the sectional area increased.

At the Howth Pier the sections showed three distinct forms assumed by the mass of materials, in consequence of the varied action of the waves. The damage done is now so extensive, that the sea threatens to make a clear breach through the works.

The sections of the Kingstown Pier showed the original form to have been a slope of 4 to 1 and 5 to 1, covered with heavy pitching, which had been repeatedly torn up, and some of the stones weighing 10 tons were carried to considerable distances: an external mole of rough work containing nearly 200,000 tons of stone which had been deposited upon the foreshore was almost all washed away; while the toe of the work beneath low-water mark, although at a greater angle than the other parts, remained undisturbed.

At Dunmore Harbour, although the long glacis with a slope of 5 to 1 is protected by pitching composed of square stones of from 2½ to 6 tons weight, and above £12,000 has been expended, it has received very extensive damage.

Many other cases of injury to sloped works were mentioned, and it was stated, that from these examples, coupled with observations upon some ancient piers in Cornwall and other exposed situations, which, although built of rough materials and with a nearly vertical sea face, had resisted the action of heavy seas, the Shannon Commissioners had determined to try, at Kilrush, a sea wall with a very slight inclination, and up to the present time it had sustained no injury, although previously the sloped work had been destroyed.

Colonel Jones, being convinced of the superiority of this form, had devoted much time to observations of the action of the waves upon works of all kinds, as well as to the various modes of using the materials composing the sea-walls; and he felt assured that if the stones were of an average size, square-jointed, and well laid, even without cement, forming an almost vertical wall of moderate thickness, springing from a point as much below low-water mark as could be conveniently attained, the work would be more durable. "Béton" (concrete) was now much used in France for the construction of sea defences: it was generally done by building caissons of ashlar, filling them in solid with "Béton," and then caulking all the ashlar joints with oakum: this kind of work was very durable.

In answer to a remark by General Pasley, Colonel Jones believed that the greatest injury was done by the receding waves, particularly if the joints of the work were not well closed.

Remarks.—Mr. Rennie took a hasty review of the moles and breakwaters mentioned by the early writers, as being thrown out for the purpose of forming harbours; Vitruvius particularly described, among other similar works, a mole constructed with a kind of concreté composed of pozzuolana. Mr. Rennie contended that engineers were not in error in taking as their guide the natural inclination of the sea shore opposite the situation where the breakwater was intended to be placed. It would be found, in following the coast of England from the perpendicular primitive cliffs of Cornwall to the flat shingle beach of Norfolk, between which places is found almost every variety of geological formation, that the profile of the sea shore differed according to the material of which it was composed and the peculiar action of the sea upon it from local circumstances. It had been shown that the force of the waves acted more prejudicially upon the point above low-water than below it; that the work would stand at a great inclination at the latter point, indeed that it was rarely injured even when all above it was carried away; that if the water was deep, the action of the waves would extend deeper: all these and many other points required to be considered in fixing upon the slope for any sea-wall; and therefore he could not accord with Colonel Jones's views in adopting an arbitrary form for all situations, without considering the exigencies of peculiar localities. He had been particularly struck with the regularity of the slope assumed by the materials at the Kingstown pier after a storm; but in that and all similar positions, the inclination of the face varied with circumstances, and with the degree of violence of the action of the waves. Among the many arguments against the proposed perpendicular form, might be mentioned the increased expense; for if built of squared stones below low-water mark, the work must be done from a diving-bell; and also that the form is objectionable for a pier, as the wave is thrown up in a mass, instead of expending its force in rolling over the long slope of the fore-shore. Mr. Telford had abandoned vertical sea-walls on these and other accounts.

Mr. Vignoles agreed to a certain extent (but not fully) with the form proposed by Colonel Jones: he believed that although the construction might be rather more costly, it would be amply compensated for by the greater durability; and he saw no difficulty in doing the work. The proposed plan he understood to be by commencing the foot of the wall only at such a depth below low-water as should prevent the violent action of the waves upon it. At Ardglass the upper portion only of the pier is destroyed; all that part below low-water remains perfectly sound: it is of ashlar of large dimensions, placed from a bell.

Mr. Gordon had seen sections of the works which were commenced for forming a breakwater at Madras: the materials reached at the highest point to within about 10 ft. of low-water, and amidst the violence of the surf of that coast the work stood undisturbed at an angle of 45°: it was composed

of "pierre perdue." At Algiers the French engineers had used extensively masses of concrete (blocs de béton), but at first they were displaced and destroyed by the force of the seas; the cubic capacity of the masses had however been increased to the extent of 2 metres square by 3 metres long; they were floated out, and allowed to drop into their places from slings; and now they succeeded perfectly. The upper part of the work is intended to be of concrete cast in caissons, the section below low-water is at an angle of 45°, and above it like an ordinary quay wall with a curved "batter."

Sir John Robison, in allusion to the depth of the wave and the power of its action at Madras, said that, during a violent storm, a quantity of pigs of lead had been cast ashore near the fort, and it was proved that they had come from a vessel which had been wrecked at more than a mile from the shore, during the siege by La Bourdonnaye.

The President observed that at the Plymouth Breakwater the largest blocks (some of them weighing from 6 to 8 tons) and the greatest number have been washed from the sea face over into the Sound; the square stones with which the fore shore is paved are placed with the utmost care, and little comparative injury has been done since that method has been adopted. Engineers now generally recommend a deep paving of squared stone in bond courses, as the best mode of construction. In order to insure the stability of the lighthouse now erecting at the extremity of the Plymouth Breakwater, a foundation of squared stones has been carried up from the natural rock, and an inverted arch turned below the level of the top of the work; and, for its farther security, a buttress is now thrown out upon the foot of the south slope, in order to prevent the stones from being carried away. It is evident, that if the materials are deposited at an inclination, any portie being displaced is only carried down to where, although strictly speaking may not be wanted, it must nevertheless assist in consolidating the mass; and the vacant spaces can easily be filled up. Under similar circumstances a perpendicular wall would suffer more severely, and probably would have fallen entirely. He therefore considered that in situations like that of the Plymouth Breakwater, which was exposed to a heavier sea than Cherbourg, a long slope for the sea face was essential. Still there were situations where the form proposed by Colonel Jones would no doubt be available, and the members were much indebted to him for the suggestion, as also for the valuable observations shown in the sections accompanying the paper: he hoped that he would continue them, and that other members, who had equal opportunities and less arduous duties to perform than the author, would give the Institution the benefit of their observations.

Mr. Macneill had seen at the mouth of the Helder, in North Holland, banks nearly vertical, constructed of sea-weed and hazel-wood fascines, backed with clay: they were exposed to a very heavy sea, and yet stood extremely well—there was considerable elasticity in them, for when a wave struck them, the vibration was felt at a distance along the bank. In other situations on the coast of Holland, the sea-banks are long slopes of sand at an inclination of 10 to 1, thatched with straw. In many places groins were built to break the length of the wave, and diminish its force; he had adopted similar groins, and found them answer perfectly.

Mr. H. R. Palmer observed that the form suggested by Colonel Jones for the faces of breakwaters did not appear sufficiently justified by observed facts; the idea was entirely of a speculative character, and was contrary to the law of nature, which should be the engineer's chief guide. Many years ago Mr. Palmer had occasion to study very carefully the motion of the shingle beach at the harbour of Folkestone, and at several other places, and the results of his observations were published in the Transactions of the Royal Society. He found that the slopes of the surface were always regulated by the force of the waves, and the angle at which they impinged; and that when the forces were at right angles with the line of beach the whole of the pebbles were brought down below the level of the acting forces. At Folkestone, when the sand was thus left bare, the surface stood at an angle of 9 to 1, and that slope resisted the force of very heavy seas. The effect of the action of the sea upon an upright surface was observable in every cliff upon the coast, and the tendency to destruction was everywhere obvious. Shingle beaches might be considered as adjustable barriers, but in the construction of piers it was necessary to adopt some precise form. When circumstances required the walls to be nearly vertical, the line of their direction should be determined with reference to the prevailing winds. Those portions of the piers of Swansea harbour which formed even only a small angle with the prevalent winds remained firm and substantial, but that part which was directly opposed, or at right angles to them, has been undermined. In a design of his for a pier in Mount's Bay at Penzance, Mr. Palmer had so arranged that the angle of the main pier should be at 5° with the line of the greatest forces. Thus, then, a horizontal slope is in fact made as a substitute for a rising one. He attributed the failures alluded to by Colonel Jones more to defective workmanship than to faults in the principle of the structure.—Mr. Palmer exhibited and presented to the Institution plans of Ramsgate, Dover, Folkestone, Swansea, and Penzance harbours.

General Pasley, in his observations of the action of the sea upon various parts of the coast, had remarked that the slope of the beach was exactly in accordance with the materials of which it was composed: if it was shingle or decomposed rock or soft material, the slope was gradual; but if the shore was rocky, the waves had not any serious effect upon the bluff face opposed to them, except in the case of chalk cliffs. He conceived, therefore, that a perpendicular wall constructed of large ashlar work well cemented, would assume the character of a rock, and all the prejudicial action of the receding wave would be avoided.

Mr. Bull stated that the banks of the river Calder in Yorkshire had been effectually secured from damage by means of stone pitching or setting, laid at an angle of from 45° to 50° with the horizon, and resting on a mass of stone thrown into the bed of the river below the level of the water in dry seasons. These loose stones had generally been laid at an inclination of about 25° or 30° where the depth at low-water was not great, but where the water was deep the lower part of the slope had been made at about 45° , returning at the upper part or near the surface of the water to the former angle of 25° to 30° . The pitching, composed of oblong stones, was laid in courses, with nearly vertical joints, having the least sectional area exposed to the action of the flood-waters. The stones were from 15 to 20 inches long, varying in their widths, and were laid on a bed of gravel, or soil, he preferred coarse gravel, as it was less liable to be washed out from behind the stones, which sometimes occurred with soil, unless it was of a strong clayey nature. Several miles of facing done by him in this manner had now been standing between seven and nine years without requiring any repairs. In a few instances, when the loose stones at the foot had been either insufficient in quantity, or so small as not to resist the action of the floods, and had been washed away, the pitching has slid down into the bed of the river without being otherwise disturbed; after it had settled, the top part had been renewed, and the original line restored. The floods in the river Calder frequently rose from 8 ft. to 12 ft., and flowed with a very rapid current, consequently the pitching had to resist a powerful action, particularly at the concave side of a bend in the river, where the action was both directly upon and along the face of the work. The loose stones below the low-water mark were seldom disturbed by the floods, and where they had been removed, no damage had been sustained beyond the sliding down of the pitching as before described; such, however, had not been the case where from peculiar circumstances a perpendicular or nearly perpendicular wall had been built instead of the pitching; in such instances a slight disturbance of the loose stones had frequently caused the destruction of the wall. Where the pitching had been backed with light soil, which was easily washed out through the joints, the stone-work had fallen into holes as might be expected, but where a good strong gravel had been used for the backing, no such instances had occurred. Mr. Bull differed from Colonel Jones's opinion as to breakwaters with a vertical or nearly vertical face, because any disturbance of the footing, however slight, must have a tendency to overthrow the wall, and that tendency would be in proportion as the angle of the wall diverged from the angle of repose; that is to say, if the wall was quite perpendicular a comparatively small disturbance of the foundation or footing would destroy the equilibrium, and the superstructure would be overthrown, but the nearer the face approached the angle of repose, the greater would be the security. He did not mean to assert that the angle of repose was the best for the face of a breakwater, or that the same angle should be preserved from below low-water mark to the top of the structure. On the contrary, he was inclined to think that a curved section, commencing from a few feet below low-water mark at an angle of 10° or 15° from the horizon, and terminating at the top at an angle of 70° or 75° would be found a good form, and if the courses of face stones were laid nearly vertically, should the footing below low-water mark be removed by the action of the waves, the consequence would be a sliding down of the upper face, which could easily be replaced at the top, as is done with respect to the river pitching. The proper angle for the loose stones below low-water mark would, he had little doubt, be that of repose, or nearly so, as Colonel Jones had shown to be the case in several existing breakwaters. The face stones should be roughly squared on the beds and joints, or what is called in the North "scappled" to the form of the curve, and laid in equal courses not quite perpendicular, but inclining a little from the direction of the prevailing wind, perhaps about 10° from the vertical line. Mr. Bull was induced to offer these remarks, for the purpose of recording a practice he had successfully applied to the protection of river banks (of which he presented drawings) and his opinion as to its applicability to the construction of breakwaters.

April 19.—The President in the Chair.

FLUSHING APPARATUS FOR SEWERS.

"On the causes of accumulation of deposit in Sewers, and on the hitherto generally prevalent mode of removing the same; with a description of a new Flushing Apparatus used for cleansing the Sewers in the Holborn and Finsbury Divisions." By JOHN ROE, Assoc. Inst. C. E.

In the Holborn and Finsbury Divisions there are upwards of 80 miles of covered sewers, in a large proportion of which there were accumulations of deposit, which, by choking the side drains and causing effluvia, became sources of much annoyance. The only remedy resorted to, was to raise the deposit to the surface of the street and cart it away: this was for many reasons an objectionable process, and a careful examination of the sewers was ordered, when it was found that many causes of obstruction existed. In sewers of the same form and inclination, different degrees of accumulation existed: this was caused sometimes by a greater run of water in one than in the other. In other cases, although the flow of water was equal, the deposit was unequal: in some situations openings having been made to insert side drains, bricks had been left in the sewer, against which considerable deposits had formed. The admission of water from collateral sewers at right angles and at different levels had also caused obstructions to the continuous flow along the main line. An example is given, where, although the collateral sewer was 3 ft. above the level of the main line, a deposit of a foot in depth

was formed for several hundred feet up the stream, while below the point of junction the sewer was perfectly clear. The insertion of gully-necks frequently caused obstructions, by permitting the access of dirt and rubbish from the road.

These facts being ascertained, the next consideration was how to remedy the defects, as the locality would not permit an alteration of level, which would give a flow through the sewers sufficiently strong to carry off the deposit. After a long series of experiments (by the author, who is engineer to the Commissioners) and trials upon several kinds of apparatus, the arrangement shown by Fig. 1 was decided upon:—it consists of an iron frame set in the

sewer with a hinged door half its height, fitting with a water-tight joint: it is opened and closed by means of a jointed rod, which is worked from the level of the street. A head of water is allowed to collect against the closed door until it is sufficiently heavy, when the door being suddenly opened, the whole mass of deposit is carried forward by the rush of water. The operation is repeated with a head of 3 ft. of water at intervals of half a mile, until the whole of the accumulation issues at the outfall, thoroughly cleansing the sewer. After this arrangement of apparatus had been some time in use, an improved form with a side entrance, as shown in Fig. 2 was contrived, and is now generally adopted in situations which admit of it.

By this simplified arrangement the stop-gate can be worked without the mechanical contrivances of the other method, and an easy access is afforded to the sewers. This latter mode is generally adopted, and the success of the plan is stated to be perfect.

All the details of the construction of the stop-gates and the sewers, as well as of several improvements in the building of the gully-holes and collateral sewers, are given, with the result of the velocities of the currents of water from heads of various heights. Drawings of all the several kinds of apparatus invented by the author were presented, and the models which were exhibited were explained by Mr. Burton, the manufacturer of the flushing apparatus.

INDICATORS FOR STEAM ENGINES.

Mr. Farey exhibited and described one of a set of indicators for steam engines, made by Mr. Penn of Greenwich, for the French Government, to be used in trying experiments on the steam vessels in their navy. The construction was the same as those made by Mr. M'Naught of Glasgow; but the instruments were larger and better proportioned. Mr. Farey availed himself of the opportunity of describing the construction, the operation of, and the qualities required in a good indicator, and then exhibited a series of indicator cards, either taken by himself or by friends whose accuracy could be depended upon. They extended from the year 1817 at short intervals down to the present time, and showed a great improvement in the application of steam in engines: in fact, Mr. Farey was of opinion that the origin and progress of the modern improvements in engines might be traced by a series of cards carefully taken at various periods, and he promised to contribute a more extended communication on the subject during the ensuing session.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

July 11.

A paper was read giving a "*Description of the Roof suspended over the Panorama in the Champs Elysées, Paris*," by M. Hittorff.

The Hon. Secretary, Mr. Bailey, observed, that although the Germans attribute the invention of panoramas to Prof. Breisig, of Dantzic, it is generally admitted that they are of English origin, and that the first was exhibited in 1793, by Robert Barker, in the city of Edinburgh. The most important building for such exhibitions, one far surpassing any at that time existing in foreign countries, was erected in London by Mr. T. Horner, and is known as the Colosseum, Regent's Park. The plan is a polygon of sixteen compartments, whose interior diameter measures about 123½ ft. The dome is constructed of timber, curved and arranged upon the principle of Phillibert de Lorme, and is covered with copper. In the centre of the building are two concentric cylinders supporting three galleries, as well as supporting the centre of the dome or roof. The rotunda since erected in Paris surpasses in magnitude even this vast edifice. Among the various designs for embellishing the Champs Elysées, M. Langbois suggested the idea of a rotunda for the exhibition of panoramas. The ground was granted to him for a term of 40 years by the Municipal Council on the following conditions:—

1. The diameter of rotunda to be 130 ft.
2. The roof to be conical, and without a central kingpost.
3. The rotunda to be lighted by a cycle of glazed sashes.
4. The intervention of any obstruction between the sashes and the wall of the rotunda (thereby casting a shadow upon the canvas) to be carefully avoided.
5. And finally, all these data to be severally complied with at the least possible expenditure.

Considering the difficulty of constructing a building of such dimensions without a central kingpost, and the great expense of arched timberwork, together with the solid structure of the walls indispensably requisite to resist the thrust of the wooden vault, the artist resolved to apply (in the construction of the new building) the principle of suspension adopted for bridges, by means of chain cables. The site of the rotunda not allowing of the adoption of stays fastened at a distance from the building, it was necessary so to contrive the buttresses that they should hold the cables and resist their tension. Their number, amounting to 12, gives a subdivision of the wall of the rotunda into arcs; and it may be considered, at the level of the stone cornice, as a polygon, whose sides adjacent to one and the same buttresses offered a two-fold force opposed to the strain of the cables. In this way the resistance was obtained nearly at the expense of the cornice and the wall; and by adopting two circles with the cables passing between these circles, the

upholding chains can be strained as required. These cables pass at an angle upwards, over vertical rods, which rest on pivots on the inner edge of the cornice wall, which is about 3½ ft. in thickness; they then rest on the outer edge of the cornice wall, and the ends of the cables are carried to the abutment walls and are there fastened. The building was commenced in October 1838, and covered in January 1832. It attains a mean height of nearly 50 ft., occupying a surface of nearly 21,653 square ft., and its circumference is composed of a mass of building above 16 ft. in depth, having three stories distributed into apartments over a space of 520 ft.; and the cost of the whole was about £13,000.

Mr. T. H. Wyatt directed attention to Forster's Patent Stoneware slabs for preventing damp rising in walls. He had found from experience, that slate was not only porous, but too brittle for the purpose, particularly where houses or buildings are likely to settle; whereas this material is not only impervious to wet, but can be made to any thickness, and sufficiently strong to resist the greatest pressure.

ON LIGHTNING CONDUCTORS.

SIR—Having erected several lightning conductors on Mr. John Murray's principle, a description of them may not be an uninteresting subject for your Journal.

The head is a copper gilt point, 2 ft. long, 1½ inch diameter in the thickest part, screwed into a ¾ in. bore copper gas tube, which is perforated just below the insertion of the head ("to allow the electric matter to act upon the external and internal surfaces," as Mr. Murray directs in his Essay on Aerial Electricity), and must be continued in as straight a line as possible to the foundation of the building, where it must terminate in a trough filled with water.

The first erected by me was at Kirkstall church, near Leeds, the spire having been struck by lightning on the 29th April, 1833; the finial and stones of the upper part were secured by a wrought iron bar formed as at A, terminating at 5 feet below the finial, a 4-inch flange being sunk into the finial and bedded upon the top stone of the spire; at the bottom of the iron bar was a washer, screw and nut, to tighten the shaft joints, and add to the security against high winds by the increased weight of the mass; the finial was fixed on to the bar with Roman cement. From this nut to the bell was a space of 40 feet, with no intermediate metal except the chain bar of iron at the base of the spire on the line of the cornice. The fluid passed through the north belfry window in a north-easterly direction, leaving the chain bar and the bell uninjured, but the north-east face of the octagon spire was burst asunder, the north-east pinnacle and part of the buttress destroyed, as also the north lucarne of the spire, and the buttress shaft cut obliquely towards

the lead flashing of the roof of the body, which was torn up, and the north west pinnacle thrown from the buttress shaft, all the corner stones disturbed, and the slates broken by the stones of the tower and spire, and considerable damage was done inside the building; the finial A and the lower stone B were so shattered that had not the molding of A been different to any other, I should not have discovered that it had been a portion of it; this was found 80 yards from the building, and the fragment did not contain 3 cubic inches; the stone was 2 ft. 9 in. high, and 2 ft. 3 in. diameter; the lead appears to have attracted the electric fluid on its explosion in the spire, yet that on the south side escaped injury altogether. When the spire was rebuilt, a copper gilt cross

was placed on the point of it, the lightning rod extending 2 feet above and attached to it, a continuous line of tube formed by 9 feet lengths, screwed together with couplings, which rests upon holdfasts of iron wrapped with old silk dipped in melted tallow; this plan of coupling is bad, as no allowance is made for the expansion of the metal, and consequently during the third summer one of the joints close under the belfry window broke, but as the lower part of the rod has not left the upper more than 2 inches, I believe it to be of little consequence as the stream would be almost continuous; this rod terminates under ground in a stone trough about 2 ft. 6 in. deep, and 18 inches square, which forms part of the line of drains round the church, made to convey the rain water from the spouts, and so placed below the drains that it must be always full. I have since this attached one to the

spire of St. Paul's church at Birkinshaw, one at Farnley, and one to Trinity church steeple in this town, (the latter 173 feet high), and one to the new church at Hendingley, 3 miles from hence; the joints are made more perfect than in my first, by soldering a portion of smaller tube about one inch down into the lower tube and 6 inches long into the upper tube (see fig. 4) below which part I fix the holdfast of painted iron, insulated with silk; the neck of a bottle would be perhaps still better as more perfectly insulating the tube, or a block of cast glass the size of half a brick, with a loop or an eye, would be more secure (see fig. 6); upon the lesser tube the upper one slides, and allows of expansion and contraction without separating the parts of the tube, which is desirable for its gravity as were the parts separated, an explosion would take place at each termination though slight, unless there were other metal nearer.

Fig. 4.

Fig. 5.—Plan of Holdfast.

Fig. 6.

The advantage of a tube is that a greater surface is exposed to the action of the electric fluid, an inch rod presenting little more than a surface of 3 inches, whereas the $\frac{3}{4}$ inch bored tube gives $2\frac{1}{2}$ inches inside and 3 outside, or from $5\frac{1}{2}$ to $5\frac{3}{4}$ inches together, and the rapidity with which the fluid passes over it, ensures it from fusion. In all cases the rod or point should be gilt to prevent oxidation, and were the tube also gilt it might be more advantageous. Since the erection of these conductors, very heavy thunder storms have passed over all the places without effecting them, whereas the new church at Doncaster had its spire partly destroyed although armed with a glass globular repeller. St. Paul's church and the new Infirmary at Huddersfield which have conductors erected under Mr. Murray's directions have escaped. So many churches have been struck by lightning in different parts of the country, that no architect should attempt to construct a spire without one of these conductors, especially as the cost is so trifling, and any village blacksmith or tinman could make the machine and attach it to either tower or spire; to ascend the spire, a short ladder may be easily raised against the face of one plane of the octagon or other figure or plan, the ladder being prepared by nailing a cross piece of wood at each end; this will give foot hold, and the rope fastened to the bottom, tightened round the base of the spire, and another rope tightened round the top of the ladder, will give a secure foot hold for raising a longer ladder to be prepared and secured in the same manner as the first, so that two or more ladders lashed together, when the height is more than can be reached by an ordinary ladder, will enable the workmen to get to the summit of any spire in the kingdom without the necessity of erecting an expensive scaffolding, should the spire have been left unprovided with a conductor, or in the case of many of our beautiful old spires, several of which have been injured. The total cost when put up before scaffolding has been removed, has not in any case exceeded 18s. per foot lineal, including the tank; it has been considered in the case of a tower with pinnacles, that each pinnacle should have a conductor: I think one would suffice, the other pinnacles being immediately upon their apex, a glass repeller. Murray observes of the lightning conductor or paratonnerre, like the paragale or hail rod, that it protects a surface around it having a radius equal to double the height of the point from the surface of the earth, or that 150 feet in height would protect a circular area 600 feet in diameter. I send you a sketch of Kirkstall church spire as it appeared after struck by lightning, with a tracing from a sketch of New Mills church, in Derbyshire, which is of the same form and dimensions as Kirkstall, having no drawing of the latter.

I am, Sir, your most obedient servant,
R. DENNIS CHANTRELL.

Leeds, 30th July, 1842.

A steam frigate, launched on the 8th ult. at Cherbourg, is the largest steamer ever built there. Another of the same power is to be launched in September. Altogether the French Government has, say the French railway papers, five first class steam frigates in hand.

YORKSHIRE ARCHITECTURAL SOCIETY.

We learn with pleasure that active steps have been taken for the establishment of a "*Yorkshire Architectural Society*," under the patronage of his Grace the Archbishop of York, and the Lord Bishop of Ripon. At a preparatory meeting, held in Leeds on the 26th July last, Dr. Hook in the chair, the following resolutions were adopted:—

"1. That a Society be formed, entitled THE YORKSHIRE ARCHITECTURAL SOCIETY.

"2. That the objects of the Society be, to promote the Study of Ecclesiastical Architecture, Antiquities, and Design, the restoration of mutilated Architectural Remains, and of Churches or parts of Churches which may have been desecrated, within the county of York; and to improve, as far as may be within its province, the character of Ecclesiastical Edifices to be erected in future.

"3. That the Society be composed of Patrons, Presidents, and Vice-Presidents; and of ordinary Members to consist of such Clergymen and Lay Members of the Church as shall be admitted according to the subsequent rules.

"4. That His Grace the Lord Archbishop of York, and the Lord Bishop of Ripon, be requested to extend their patronage to this Society.

"5. That the Lord Lieutenants of the three Ridings of the County of York be requested to accept the office of Presidents.

"6. That the following Noblemen and Gentlemen be requested to accept the office of Vice-Presidents:—

* * * * *

"7. That new Members be proposed and seconded by Members of the Society at one of the meetings, and elected at the next, and that Honorary Members be elected only on the nomination of the Committee.

"8. That Rural Deans within the County of York be considered on their signifying their intention to become Members, as *ex officio* Members of the Committee.

"9. That each Member shall pay ten shillings at his admission, besides an annual subscription of ten shillings, to be due on the first of January in each year; but that the admission fee of those who may become Members before the 31st December next, be considered as their subscriptions for the current year.

"10. That any Member may compound for all future subscriptions by one payment of five pounds.

"11. The affairs of the Society shall be conducted by a Committee, composed of the President, Vice-President, and thirty-six ordinary Members, (of whom five shall be a quorum), who shall be elected at the Annual Meeting, and of whom twelve at least shall have been Members of the Committee of the preceding year.

"12. That the Committee elect out of their own body, a Chairman, and so many Secretaries as may be rendered necessary by the large extent of the county.

"13. That the Society meet for the reading of papers, and the dispatch of ordinary business, in the spring and autumn of each year: the meeting in autumn to be considered the public annual Meeting.

"14. That each Member be allowed to introduce a friend to the ordinary Meetings of the Society.

"15. That donations, both of money and of books, plans, casts, and drawings, be solicited, and that the Committee be empowered to make such additions to the collection of the Society as may be deemed necessary.

"16. That the library, casts, and portfolios of the Society, be under the charge of the Secretaries.

"17. When the Committee shall consider any paper worthy of being printed at the expense of the Society, they shall request the author to furnish a copy, and shall decide upon the number of copies to be printed; provided always that the number be sufficient to supply each member with one copy, and the author and secretaries with twenty-five copies each; the remaining copies may be sold at a price fixed upon by the Committee. All other questions relating to publishing papers, and illustrating them with engravings, shall be decided by the Committee.

"18. That Christopher Beckett, Esq., be requested to accept the office of Treasurer; that E. J. Teale, Esq., be requested to accept the office of auditor of the Society's accounts; and that the Rev. Geo. Ayliffe Poole, Rev. Joshua Fawcett, and Samuel Wilkinson, Esq., be provisional Secretaries, until the office be filled according to rule 12.

"19. That the Oxford Architectural Society, the Cambridge Camden Society, the Exeter and Lichfield Diocesan Societies for Promoting the Study of Ecclesiastical Architecture, and the Durham Architectural Society, be requested to accept free admission for their Members to all the meetings of this Society; and that every attempt be made to reciprocate in all good offices with Societies of kindred objects and constitution."

CAOUTCHOUC CEMENT.

Specification of a Patent granted to ALFRED JEFFERY, of No. 8, Lloyd-street, Pentonville, Gent., for a new method of defending the sheathing of ships, and of protecting their sides and bottoms.—[Sealed 29th April, 1841.]

This invention consists in the production of various solutions and mixtures, for preparing oakum for caulking, and paying the seams, and coating

the sheathing of ships. The solutions are three in number, viz., turpentine caoutchouc solution, naphtha caoutchouc solution, and coal-oil caoutchouc solution.

The turpentine caoutchouc solution is formed by dissolving one part, by weight, of caoutchouc, in twelve parts, by weight, of spirits of turpentine.

The naphtha caoutchouc solution consists of one part of caoutchouc, dissolved in twelve parts of rectified coal naphtha.

The coal-oil caoutchouc solution is produced by dissolving caoutchouc in coal-oil, the proportions being the same as in the two former solutions.

The mixtures are asphaltic mixtures, Nos. 1 and 2, and lac mixtures, Nos. 1 and 2.

The asphaltic mixture, No. 1, consists of two parts, by weight, of powdered asphaltic, dissolved in one part of the naphtha caoutchouc solution.

The asphaltic mixture, No. 2, is composed of two parts, by weight, of asphaltic, dissolved in one part of the coal-oil caoutchouc solution, and to four parts of this mixture, one part of a solution of corrosive sublimate is added. This solution is prepared by dissolving two parts of powdered corrosive sublimate in three parts of white naphtha, in a glazed earthenware vessel, and then adding three parts of coal-oil to it.

The lac mixtures, Nos. 1 and 2, are prepared in a similar manner to the asphaltic mixtures, with this exception, that lac is employed instead of asphaltic.

Oakum is prepared for caulking by soaking it in either the turpentine or naphtha caoutchouc solutions; the superfluous solution is then pressed out, the fibres separated, and the oakum being dried, is ready for use. The asphaltic mixture, No. 1, or the lac mixture, No. 1, is used for paying the seams.

The sides and bottoms of ships are protected by a coating of the asphaltic or lac mixtures, one-eighth of an inch thick; either of the mixtures No. 1, may be applied to the parts above water, or for the first coat of the parts below water; but one of the mixtures No. 2, must be used for the remaining coats, which the under parts of the vessels receive. The mixtures are applied, when hot, by means of a brush, each coat being allowed to dry before the following one is laid on, and the surface of the last coat is smoothed by the application of heat.

The patentee claims, firstly, the method, by the means herein described, of defending the sheathing of ships, and of protecting their sides and bottoms; secondly, the application of caoutchouc for the same purpose; and thirdly, the application of lac for effecting the same object.

STEAM NAVIGATION.

GOVERNMENT STEAMERS.

We are glad to see that Government is beginning to form a fleet of steamers, on an increased scale. We have the *Penelope*, 42-gun frigate, now having 60 ft. added to her length at Chatham; she is to have a pair of the Gorgon engines of 625 h.p., by Messrs. Seaward and Capel. The total cost of the engines will be £28,000: this vessel is in a forward state. Another vessel of 1650 tons burden is to be built under the superintendence and from the lines of Mr. Oliver Lang, master shipwright of Woolwich dock yard, and to have a pair of engines of 800 h.p. Another vessel of equal magnitude is to be built at Chatham dock yard, which was intended to be called the *Dragon*, but we are happy to announce that she is to be named the "JAMES WATT." This is as it ought to be: we have here a name revered by every engineer, and we may say by every Briton. She is, we understand, to have the double cylinder direct action engines of Messrs. Maudslays and Field. We hope that Government will not stop here; we must have at least a dozen of such vessels; we shall then only be just a-head of the French Government, who, we know, are constructing steam vessels of a larger magnitude than any of our present class. This must not be allowed; we must have the ascendancy of the ocean. We have both the metal and the men to construct engines upon a large scale, at a *short notice*. They only want the support of the Government; and with such aid, we shall be able to keep Old England a-head of all the world.

The Queen.—This steam boat, which was engaged last month to convey the Lords of the Admiralty from London to Woolwich, was built by Messrs. Rennie. Her performance is remarkably good; at her first trial, we are informed that her speed at the measured mile was equal to nearly 16 statute miles through the water per hour, with 32 strokes per minute. The vessel is 160 ft. long, 16 ft. 6 in. beam, and 8 ft. deep; burthen 219 tons: draught of water 4 ft.; midship section of immersion 44 ft. She has two engines of 35 h.p. each, or as 1 h.p. to 3 tons. The weight of engines, including water in boilers, wheels, &c., complete, 35 tons. Nothing can be more beautiful than the motion of the vessel through the water, which it seems to divide without a ripple. She is perfectly stable and stiff; in going down the river from Long Reach Tavern to Gravesend Church, the distance of 9 miles, with tide, was done in 27 minutes.

The *Megara steam vessel* has been fitted with tubular boilers by Messrs. Seaward and Co., being the first man-of-war steam vessel fitted with boilers of that description.

The *Rocket*, iron steam vessel, built by Messrs. Fairbairn and Company, at their establishment in the Isle of Dogs, for the service of Government, has been taken charge of by the officers of Woolwich Dockyard.

The *Meteor* steam vessel, Lieutenant-Commander G. Butler, towed down to Greenhithe at the beginning of last month, a chain lighter with some buoys and mooring chains, to be laid down in that part of the river under the direction of Mr. Tinmouth, master-attendant of Woolwich Dockyard, as it is intended in future that the vessels built, refitted, or otherwise altered here, be swung at Greenhithe, in order that the variation of their compasses may be adjusted under the immediate superintendence of Captain Johnson, previous to their proceeding to sea.

The Montezuma Steam Frigate.—At a trial voyage of the above-named magnificent vessel took place from Blackwall to the Lower Hope and back. It is stated that she steamed at the rate of 10½ miles an hour against tide both ways, the engines making 21 strokes per minute. The *Montezuma*, although of the burden of 1,100 tons, draws no more than nine feet water when fully equipped, and is built to carry two swivel guns, 68-pounders, on the upper deck, besides the usual number of small guns. She was constructed at the yard of Messrs. Wigram and Green, at Blackwall, and her engines, which are of 300-horse power, and constructed on almost a similar principle to those on board Her Majesty's steam-frigates *Driver*, *Gorgon*, *Styx*, &c., were supplied and fitted by the firm of Messrs. Seaward and Capel. These engines can have the steam cut off at half stroke, so as to act on the expansion principle.

Canada.—An iron steamer, for the use of the royal navy on Lake Ontario, has lately arrived out from home. It came, of course, in pieces, but the Government having sent out competent persons, it is to be put up forthwith. In the same vessel which brought out the iron steamer arrived the magnificent engines by Messrs. Boulton, Watt, and Co. of the steam frigate *Cherokee*, now almost ready for launching.—*Times*.

MISCELLANEA.

WOOLWICH DOCK YARD.—One of the best pieces of granite masonry that we have ever seen is now executing at this dockyard, in the construction of the new dry dock, it is built with blocks of granite of large dimensions, laid in radiating courses, and worked with great precision and hammer dressed. Messrs. Grissell and Peto are the contractors to whom this work is intrusted under the direction and superintendence of Messrs. Walker and Burgess. A powerful steam-engine by Boulton, Watt, and Co. has been erected for the purpose of withdrawing the water within a very limited time when vessels are docked to be examined. Some idea may be formed of the magnitude and complete arrangement of the new dock when it is stated that it is sufficiently large to admit, for the purpose of being docked, ships of equal dimensions to the *Trafalgar*, of 120 guns, and that the volume of water requisite to float vessels of that size could by the power of the steam engine be completely withdrawn into the basin at high water or into the river at ebb tide in about 20 minutes, and in the event of the vessel examined being found sound and not in want of any repairs she might again enter the river ready for service without losing a tide. These are improvements in celerity of movement which cannot fail to prove of great importance to the country in the event of war with any foreign Power at a future period. The engine connected with the dry dock has been erected in a handsome and substantially constructed building, and on the top an iron tank has been placed capable of containing 190 tons of water, and which will always be kept full in case of accidents from fire at the end of the yard in which it is situated.

Stucco Paint Cement.—We have examined some specimens of this cement upon plaster, slate, and wood. It has all the appearance of stone, and forms a complete impermeable coating, and answers the combined purpose of both paint and cement; it is manufactured and sold in a fluid state, like white lead, and when used it is mixed with sand, in the proportion of 3 of the latter to 1 of the former, and laid upon brickwork in the usual manner. If used upon brick, it requires about 7 lb. of the fluid cement, and if upon plaster about 4 lb.: it is sold at 12s. per cwt. For damp situations, and for walls exposed to a south-western aspect in the country or on the sea side, it will be invaluable. Specimens may be seen at the Bernasconi Gallery, Chienestreet, Bedford-square.

Hereford.—St. Nicholas' New Church was consecrated 11th August last. This church is beautifully situated at the Friars, a very short distance from the site on which the old church stood, leading to the Barton, extending east to west from Victoria-street to Friars-street. The style of architecture is that of the early English; the plan is a parallelogram, with a tower at west, and chancel and vestry at east, projecting beyond each end. The walls are built of neatly hammer dressed wall stone, the buttresses and dressings being tooled. The sides are divided into compartments by buttresses in two stages; the upper part terminating with coping of parapet by weathered canopies. In each compartment are placed lancet windows, with neat hood-moulds, terminating on carved bosses. The chancel is flanked by plain buttresses and octagonal pinnacles with carved finials; in the gable is an open trefoil for ventilation, and below are three lancet windows, united by

their hood-mouldings, terminating upon carved bosses, and glazed with ground glass, surrounded by a border of rich stained glass, producing a soft and beautiful light. The tower is flanked by massive double buttresses, the lower and upper offsets terminating in weathered canopies; in the centre of the tower is the west entrance, the tower forming a vestibule, in which is the gallery stairs. On the south side is a neat porch with inner folding doors. Down the centre of the church is a very spacious aisle fitted with free seats; upon each side is a double row of pews with stall ends and cast heads. Over the west entrance is an organ loft and gallery with cast iron railings in front. The pulpit and reading desk are on each side the aisle leading to the altar, which is approached by two steps, and surrounded by a handsome railing. The building is ceiled to the rafter, showing the timbers of the roof, the trusses of which are filled with tracery. The church is 81 ft. long and 48 ft. 6 in. wide in the interior, and contain 800 sittings, 350 of which are free. The entire edifice is highly creditable to the architect Mr. Duckham.—*Hereford Times*.

Kentish Town Church.—A view of the exterior and interior of this intended church, designed by Mr. Bartholomew, has been published. It was chosen out of a competition of 5. It is to be built from a grant of £800 by the Church Commissioners, and from private subscriptions, towards which the Queen Dowager, the Bishop of London, Earls Dartmouth and Mansfield, and many of the wealthy inhabitants of the neighbourhood contributed largely. The site is that of the present parochial chapel: the cost is to be, including the materials of the present chapel, about £6000, and the number of persons to be accommodated 1650. The altar, chief entrances, and principal façade, are towards the east, whence peculiarities of confirmation result. The plan is a parallelogram with two very short transepts. The western of these transepts spreads out the rear elevation, as seen over the Hampstead fields, to great breadth; these are flanked by turret staircases, and the eastern transept being unencumbered by galleries, leaves a free and open chancel. Below the great altar window a low apsis projects, for the purposes of a vestry, and the altar recess is flanked by two steeples about 50 ft. high, to contain staircases, bell, clock, &c. It is the architect's wish to raise these by an extra fund to upwards of 130 ft. The internal effect and construction are altogether original: arches span the fabric in all directions, interchangeably counter-abutting each other, rising from four iron columns and four piers, containing cores of iron. The arches which span the nave spring from half length figures of the four evangelists. Wherever the arches reach the external walls they are restrained by masonry buttresses, detached at bottom from the walling, and ascending with lofty pinnacles, giving great strength and play of external effect. The roofing is peculiar: all the rafters are rendered passive by being laid horizontally; those to the clerestory bear upon arches about 7 ft. apart, and the roofs of the aisles, by being gabelled against the clerestory, both restrain any ultimate derangement which these arches might suffer, and increase the picturesqueness of the flanks of the building. All the roof work is to be stained oak colour; there is to be no plastering whatever about it. The body of the church is to be illuminated by six plain lancet windows, four three-light columnar windows with tracery, and nine ornamental rose windows. The altar, besides the great painted window, is to have four smaller windows to be filled with stained glass containing the decalogue, creed, &c. with sacramental borders of corn and vines; and below these again will run all round the altar recess a series of canopies, supported upon slender columns with foliated capitals of stone (already in existence), and which are of rare beauty. In the centre, under the altar table, will be a relief of the Coming to the Holy Sepulchre. The material is to be externally white brick, and all the canopies, capitals, (except those last-mentioned) finials, crosses, shields, panels, and most of the other decorations, are to be of terra cotta or vitrified stone, durably embossed into the walling, and not attached by cramps and pins. The style is the decorated early English, or early decorated, the combined mass and slenderness of the French cathedrals, Lincoln cathedral, and other buildings of similar date, being imitated: all the capitals, of which there are some hundreds, are foliated.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 29TH JULY TO THE 25TH AUGUST, 1842.

Six Months allowed for Enrolment, unless otherwise expressed.

THOMAS BELL, of Saint Antisl, Cornwall, mine agent, for "improvements in the manufacture of copper."—Sealed July 29.

JULES LEJEUNE, of Regent's park, engineer, for "improvements in accelerating combustion, which improvements may be applied in place of the blowing machines now in use."—July 29.

JOHN STEPHEN WOOLRICH, of Birmingham, chemist, for "improvements in coating with metal the surface of articles formed of metal or metallic alloys."—August 1.

ALFRED JOHN PHIPPS, of Blackfriars-road, gentleman, for "improvements in paving streets, roads, and ways."—August 1.

JOSEPH WHITWORTH, of Manchester, engineer, for "improvements in machinery or apparatus for cleaning roads, and which machinery is also applicable to other similar purposes."—August 2.

JOHN DRY, of Beverley, agricultural implement maker, for "improvements in thrashing machines."—August 2.

SAMUEL CARSON, of Covent Garden, gentleman, for "improvements in purifying and preserving animal substances."—August 3.

ARCHIBALD TURNER, of Leicester, manufacturer, for "improvements in the manufacture of muffs, tippets, ruffs, mantillas, cloaks, shawls, capes, peleries, boas, cuffs, slippers, and shoes."—August 3.

JOHN LEE, of Bermoodsey, gentleman, for "improvements in wheels and axle-trees to be used on railways, and in machinery for stopping on, or preventing such carriages from running off railways, which improvements may also be applied to other carriages and machinery."—August 3.

CHARLES HENRI PERREN, of Lombard-street, London, for "improvements in the construction of certain parts of the mechanism used in watches and chronometers, which improvements are also applicable to some kinds of clocks."—August 8.

DAVID NAPIER, of Millwall, engineer, for "improvements in steam engines and steam boilers."—August 9.

THOMAS WALKER, of Birmingham, stove maker, for "improvements in stoves."—August 9.

RICHARD FORD STURGES, of Birmingham, manufacturer, for "an improvement in the manufacture of Britannia metal and plated wares."—August 10.

DOMINIO FRICK ALBERT, of Cadishead, Doctor of Laws, manufacturing chemist, for "a new combination of materials for the purpose of manufacturing a manuring powder."—August 10.

MOSES POOLE, of Lincoln's Inn, gentleman, for "improvements in paving or covering roads and other ways."—August 11.

JOSEPH BETTELEY, of the Brunswick Anchor Works, Liverpool, chain cable manufacturer, for "improvements in windlasses and machinery for moving weights."—August 11.

JOHN THOMAS BETTS, of Smithfield Bars, gentleman, for "improvements in covering and stoppering the necks of bottles." A communication.—August 11.

GEORGE ROBERTS, of Liverpool Road, miner, for "improvements in the construction of lamps."—August 15.

WILLIAM RAYBOULD, of Clerkenwell, brass founder, for "a new or improved soldering iron."—August 18.

GEORGE JOHN NEWBERRY, of Cripplegate buildings, artist, for "improvements in producing damask and other surfaces on leather and other fibrous substances and fabrics."—August 18.

NATHAN DEFRIES, of Fitzroy-square, engineer, and NATHANIEL FORTESCUE TAYLOR, of Mile End, engineer, for "improvements in meters for gas and other fluids."—August 18.

WILLIAM RIDGWAY, of Stafford, earthenware manufacturer, for "a new method of conveying and distributing heat in ovens used by manufacturers of china and earthenware, and brick, tile, and quarry makers."—August 18.

GOLDSWORTHY GURNEY, of Great George-street, gentleman, for "improvements in apparatus for producing, regulating, and dispersing light and heat."—August 18.

RICHARD ELSE, of Gray's Inn, Esq., for "improvements in machinery or apparatus for forcing and raising water and other fluids."—August 18.

THOMAS HENDRY, of Glasgow, mechanic, for "improvements in machinery for preparing and combing wool, and other fibrous materials."—August 25.

DAVID REDMUND, of City Road, engineer, for "improvements in hinges or apparatus applicable to suspending or closing doors and gates, and other purposes."—August 25.

ERRATA.

In Mr. Hodgkinson's paper, at top of col. 1, p. 275, instead of the third column of the table, read Ratio of mean tensile to crushing strength.

1 to 0.55

1 to 6.6

1 to 7.8

1 to 10.5 or 8.9 taking the hardest only.

South-Eastern Railway—line 25, page 262, instead of the pressure being "increased in the ratio of the square of two to unity," it should be "increased in the ratio of the square root of two to unity."

Page 251, col. 1, line 28, for *Avaca* read *Cloaca*.

TO CORRESPONDENTS.

We have received from Mr. Sevrell, C. E., of New York, a drawing and description of a disconnecting crank for marine steam engines, dated Feb. 1842; we do not consider it so efficient or so simple as that of Mr. Trewhitt, described in the Journals of last Feb. and June.

"O. T."—We feel obliged for his communications—they shall be inserted next month.

Mr. Robertson's Paper on Railway Signals we have been obliged to postpone for want of room.

We have been obliged to postpone our plate until next month, and instead we have given an extra sheet, with numerous wood engravings.

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant, addressed to the Editor, No. 10, Fludger Street, Whitehall.

1 Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume.

Alex. Hall, Publisher 67 Prince's St. East

"TRIBUTE TO THE MEMORY OF SIR CHRISTOPHER WREN."

WITH AN ENGRAVING, PLATE XII.

Names of the Public Buildings referred to in the annexed Plate.

THE publication of an engraving from Mr. Cockerell's design, illustrating all the principal works of Wren, appears to us a fitting opportunity for laying before our readers some account of that great man, and a chronological list of his works. The drawing by Mr. Cockerell, contains no less than sixty public structures, admirably grouped together, so as to produce a beautiful picturesque effect; it attracted much attention when exhibited at the Royal Academy in 1838. Now, by the spirited enterprise of Mr. Hill, of Edinburgh, the publisher, a splendid line engraving on a large scale has been executed by Mr. Richardson, in the first style of art, which will place this work at the command of Wren's numerous admirers in England, on the continent, and in the new world. We heartily commend it to their patronage. The key-plate, which we insert in the present number, will, in our volumes, be always accessible for reference, while the engraving itself forms an abiding record of the labours of the most distinguished master in English architecture, and a work so immediately connected with the sympathies of Englishmen and of English architects, we hope to see in the studio of every member of the profession.

CHRISTOPHER WREN was born on 20th Oct, 1632, at East Knoyle, in Wiltshire, of which parish his father, Christopher Wren, Dean of Windsor, was rector. In this parent he had the advantage of possessing a man of learning, by whom his precocious talents were nursed, and from whom he derived his attachment to mathematical studies. After studying at Westminster School, one of the most illustrious seminaries in England, he entered at All Souls' College, Oxford, where he took the degree of Bachelor and subsequently of Master of Arts, and afterwards acquired a Fellowship. For success in life he possessed strong guarantees in the shape of extensive and profound learning, and powerful connexion. The son of a dignitary who had rendered good service to the royal cause, he was also the nephew of Bishop Wren, a most violent Carlist partisan. His sister, too, is recorded as being in the good graces of Charles II. for curing him of a wound in the hand by her surgical skill. History sayeth not, but perhaps like Newton, Marlborough, and others of his eminent contemporaries, Wren might have been indebted for some portion of advancement to feminine interest. However leagued with the royal party, he was of too easy a disposition to allow such prepossessions to stand in his way, for we find him, early in life, commended to the notice of the Lord Protector Cromwell, and, like Dryden, commencing his career under his patronage. The Protector even offered him to

allow his uncle Bishop Wren's release from the Tower, but that furious zealot liked martyrdom too well to accede to the conditions. The young Wren must, indeed, have been, as he is represented, of very unworldly character to charge himself with such a mission; for instead of finding it received as a boon, it was rejected by the Bishop with the greatest indignation. It was not the fashion of that day to let party stand in the way of personal advancement, and young Wren continued his court to the "greatest man" of the day, and pressed forward into the career of scientific advancement, which was opened to him. Wren's chief glory is in some degree his misfortune, the height of his fame in one department has obscured his proficiency in others, and in becoming the great architect of his day, he has lost the fame of being one of its greatest philosophers. To his precocity we have already alluded, and to his inclination for mathematical studies; he was placed in a school well calculated to bring forth his energies; for in those days, Newton being unborn, Oxford had not yet ceded to her younger sister mathematical supremacy. Oxford was also the cradle of the Royal Society, in which Wren was early enrolled, and he had thus full scope for the exertion of his talents, and abundant promise of their being duly appreciated. As a mathematician Wren ranks as one of the first of his day,* and to his last day, he continued devotedly attached to that favourite pursuit. As his youth began with that study, and his earliest compositions were directed to it, so the last years of his life were spent in the correction of the labours and observations of sixty years. It was Wren who successfully accepted Pascal's famous challenge to the mathematicians of England, and returned the defiance with a problem which Wren himself was alone able to answer. As a practical and theoretical astronomer, he distinguished himself by his observations on the cometary system, and on the satellites of Jupiter, and by anticipating Huygens in assigning the theory of Saturn. He suggested the use of a certain part of the length of a degree as a standard of measure. For the improvement of navigation and the instruments used in that art, in surveying and in the sciences of observations, he gave to the world many valuable inventions. He is a claimant for the honour of inventing the barometer, and many of its practical applications. For the study of optics he equally exerted himself; he applied himself to perspective and to the devising of optical instruments. If such was the varied range of his mathematical pursuits, natural studies did not less occupy

* See Hutton's Mathematical Dictionary, article Wren.

him. He was an attentive student of physiological phenomena, and the acknowledged assistant of Scarborough and Willis, to whose works he contributed anatomical drawings. His biographers claim for him the invention of the process of injecting liquids into the veins of living and dead animals; and also, in furtherance of the study of natural history, the origin of what is called micrography, or the delineations of objects as seen by the microscope. In these studies he was the author of many useful experiments, among others, hatching eggs by artificial heat. On meteorology we have a very interesting paper by Wren, pointing out a course of experiments, similar to those since carried out by the British Association, with hints for the improvement of the anemometer and hygrometer. As an artist, his architectural reputation must speak for him, and we have alluded to his eminence in the delineation of objects of natural history, in which he had the patronage of Charles II. In All Souls' College, Oxford, are preserved many of his architectural designs, and also some of his working drawings, doing in the early part of his career everything himself. For the invention of mezzotinto engraving he is one of the claimants, and also for that of many instruments used in drawing. We have yet to speak of his mechanical ingenuity, which was one of his boyish characteristics, having at an early age devised an orrery, which he dedicated to his father, and a double pen, which received the approbation of the Lord Protector Cromwell. In all kinds of what are called mathematical and optical instruments, his ingenuity was, as we have said, prolific, and his skill was ever ready, in the course of the great works in which he was engaged. In a knowledge of mechanical processes, and an acquaintance with the several trades, he had few rivals in his day; as a civil engineer he has also left proofs of his ability. His invention was most ready, like that of Watt too ready; like that great man, too, he rarely pursued his ideas to completion, and was too negligent to put them into a definite form; the best thing that happened to his suggestions was to become the spoil of pirates and plagiarists, to be secretly conveyed to the continent by Oldenburg, or to be appropriated by Hooke. In reference to these failings, we are by no means unwilling to believe, that if Wren were indeed the inventor of mezzotint, that he would be pleased rather than otherwise with its appropriation by a patron so powerful as Prince Rupert. We have now to speak of his literary attainments, for he was the true admirable Crichton. He made his debut with Latin verses above the youthful standard, and we find him noted by Sprat, in after years, as translating Horace into English verse. In Greek, Latin, Italian,* French and English, he was well versed, and his Latin and English prose, as displayed in the few fragments left by him, are far purer than was the wont of that day. As an antiquary he has given us specimens of his labours, and it is deeply to be regretted that, with his love of letters and good skill in them, we should have so few memorials of what he was able to do. Such was Wren, a master in every branch of learning, a contributor to its advancement by his example and exertions on every occasion, admired by his contemporaries, and presenting one of the brightest instances of early and diversified talent matured to produce the most distinguished results.

We have now to trace Wren in his career, to see how his valuable acquirements were pressed into the public service. He early received a Gresham professorship, the Savilian professorship at Oxford, and the dignity of Doctor of Law, and distinguished himself in the discharge of his duties. On the return of Charles II., his connexion could not fail to launch him on the full tide of royal and ecclesiastical patronage, and from that period we find his progress rapid. His rooms at Gresham College had become the resort of the Royal Society, and on the incorporation of that body by that patron of science, Charles II., he became one of its chartered fellows, and subsequently for two years its president. In 1663, he received from the munificent Archbishop Sheldon, his first architectural employment, the construction of the theatre at Oxford, for the accommodation of four thousand persons, an enterprise of which he well acquitted himself. He subsequently received a commission from his uncle the

Bishop, to build the chapel of Pembroke College, Cambridge; and about the same time was employed to report on the repair of old St. Paul's, his designs for which were fortunately not carried into effect. He was now the Deputy (and de facto) Surveyor General to the King, and in 1665 made an excursion to Paris, where he employed himself in examining the progress of the arts, and the wonders of the prosperous era of Louis le Grand.

We now come to the epoch of Wren's life, which was to consign him to architecture as his chief pursuit—this was brought about by the deplorable fire of London, in 1666, and the consequent necessity for rebuilding the metropolis. Then, as in the recent case of the fresco painting of the Houses of Parliament, the Government had recourse to the continent, and Perrault was invited to superintend the building of the new city, but fortunately could not come. We hope that the rejection of Cornelius will produce no deeper regret than the absence of Perrault. After the fire, projects poured in upon the Government for laying out the city upon a regular plan, Hooke and Evelyn sent in theirs, and Wren sent in his. After-experience has perhaps taught us that no permanent evil has resulted from the non-adoption of any one of them. Wren was appointed one of the Commissioners for rebuilding St. Paul's, Surveyor for rebuilding the city, and in 1669, King's Surveyor General, and a weight of duties was imposed upon him, which he managed to discharge, and at the same time not to neglect his scientific pursuits. Not only had he to design nearly all the public buildings, which had been destroyed, but to build and repair palaces elsewhere, to act as a Commissioner of arbitrations, to report on public improvements, to check accounts of all kinds, and to lay out and construct roads and sewers. In laying out the city, we have greatly to admire his regard for the health and cleanliness of the population, the attention he paid to draining, and we may record his opinion against the practice of burying in towns. Ventilation was one of the subjects to which he had turned his attention; and the internal economy of his buildings was not neglected. He it was who aided in the compilation of the rules for the governance of Chelsea Hospital.

In the midst of these labours, in 1672, Wren received the honour of knighthood; and in 1674, married a daughter of Sir John Coghill, and on her death, a daughter of Viscount Fitzwilliam, in the peerage of Ireland. By both wives he left issue. In 1680 and 1681 he was President of the Royal Society. In 1685, in the revolution parliament, he served as member for Plympton, in Devon., and subsequently for New Windsor and Weymouth. Of his parliamentary duties we have no account, but we suppose he was merely put in as a government officer to supply a *fagot* vote on ministerial questions. It might be worth inquiry whether Sir Christopher voted for the ejection of James II. or not. At any rate, he was a favourite of both William and Anne, the former of whom made him stand godfather to the cloisters and other barbarisms at Hampton Court, of which the King took the responsibility. To testify his obligations to Queen Anne, Sir Christopher placed at Windsor, in 1714, a statue of Prince George of Denmark, the Prince Consort. Among his notabilia, we must observe that he was grand master of the Freemasons, and is by many good authorities considered the founder of that order.

Sir Christopher Wren built St. Paul's, several palaces, many public buildings and works of art, and fifty churches; and he attained at home and abroad the renown of a distinguished philosopher and great artist. In 1718, the Germans having got possession of the English throne, commenced their career of vandalism, by depriving Wren of his Surveyor Generalship in the 86th year of his age, and 49th of his service, an act which met with the execrations of that age, and the contempt of the succeeding. His time and his unimpaired faculties were now devoted to his mathematical works, and his relaxation was yearly to be conveyed to contemplate his great work. In such pursuits he died happy, on the 25th February, 1723, and was honoured with a public funeral, and a sepulchre in his own immortal monument.

Rarely has there been a man, who cared less for the troubles of this world, or who laboured so hard for such trifling remuneration. His salary for superintending the rebuilding of St. Paul's, was £200,

* Birch's History of the Royal Society, Vol. II, p. 72.

"and for this," as the Duchess of Marlborough said, "he was content to be dragged up in a basket three or four times a week." This salary was, however, in the eyes of his owlish brother commissioners too much, so that at one time they stopped half of it, under pretence of obliging him to hasten the completion of the work. Among other persecutions, they forced him against his own opinion to alter the design of his building, to put a balustrade on the outside, and to have the interior of the dome decorated in perishable painting. Wren, nevertheless, notwithstanding his small allowances, did not die poor, he accumulated enough to leave an estate behind him.

As a man of science and of varied attainments, we have said enough to show Wren's greatness; we have now to consider him as an artist; and here we may observe, that of late years there seems as much disposition to underrate Wren, as formerly the contrary bias prevailed. Why this should be we do not well see—why Wren should be tried by another standard than Palladio or Vignola, or Perault and Mansard. This, however, is part of the fashion, we may say, part of the errors, of the day. The gentle madness of the age is to place the height of art in the mechanical copying in milk-and-water colour of some ancient edifice, and Wren's defect was a too general neglect of all rules of art. So far the antipathy is readily accounted for, but it is not on these grounds that the public will be induced to form its decision as to Wren's merits. The public, whatever may be its failings as to technical criticism, whatever may be its lenient tendency to grant magnificence on the promptings of ignorance, has still some claim to exercise the "*vox dei*" in matters of art, and will not sink, for trifling errors, preponderating merits. The fault of Wren, decidedly, was his unacquaintance with the details of his art, or inattention to them, and in the weighty labours imposed upon him, there is great reason to fear that he too often made his design on the promptings of the moment, without discrimination, and without subsequent correction. His poverty on many occasions, his misplaced luxuriance in others, his want of breadth and repose, weakness of proportions, and disregard of styles, are defects, which, seen unmitigated among his successors, inspire disgust,—but Wren had redeeming qualities. He had the eye of an artist, he had great resources in unrivalled constructive skill, and when he chose, knew equally how to unite the novel, the grand and the picturesque. When, moreover, we consider him in relation to the age in which he lived, the equally flagrant errors of his predecessors and contemporaries, and that his labours in this country were unexampled, he must be acknowledged to be a great name in art. More errors, perhaps, can be detected in a single great work of Wren, than in all the productions of a modern architect, but his superiority remains unimpeached. Thus the last number of Blackwood contains a prodigious mass of nonsense extracted from Macbeth, and yet the merits of that great work of Shakspeare are still unshaken. Many of Wren's faults arise from the attempt after novelty, a sin not too often committed now-a-days; but still "*une belle faute vaut mieux qu'une mediocre bêtise*." As to Wren's neglect of the gothic and defacement of it, however we may regret it, it was a creed as orthodox in his day as the persecution of papists, and the concoction of popish plots. Wren was only mad with the rest, but at least he left some specimens of gothic more decent than anything which appeared from his time to that of Horace Walpole. One of his characteristics was a hankering after domes and skylights, which he early manifested in his design for the repair of old St. Paul's. Wren had at his disposal greater means than perhaps any other architect ever possessed, and on the whole, he made a noble use of them; but we cannot observe without regret, that sums much larger than the barn-church Commissioners allow in these days, were frequently expended without producing any effect.

As examples of Wren's most admired works, we may enumerate St. Paul's Cathedral; the steeples of Bow Church; St. Bride's, and St. Magnus the Martyr; Greenwich Hospital; and St. Lawrence, Jewry, Cateaton Street.

Of interiors—St. Stephen, Walbrook; St. Clement's Danes; St. James's, Piccadilly; Trinity College library, Cambridge; St. Mil-

dred's, Bread Street; St. Bride's; St. Mary, Abchurch; and St. Bennet's, Threadneedle Street.

Of the pointed style—St. Dunstan's in the East; St. Michael's, Cornhill; St. Mary, Aldermay; All Souls' College, Oxford; and St. Alban's, Wood Street.

Of constructions—the dome of St. Paul's; the Monument; the spire of St. Dunstan's in the East; the roof of the Sheldonian Theatre; the repair of Chichester Cathedral; the dome of St. Antholin's, Watling Street, &c.

For drawing up these notices, we have availed ourselves of several works, largely of those of Mr. Godwin and Mr. Elmes, but we have felt that the life of Wren is yet to be written. The Parentalia is only a chartulary, and Mr. Elmes' work, however copious, not exhausting the subject, and containing much heterogeneous matter. It is, nevertheless, at present, the only life of Wren, which deserves the name. Mr. Cockerell has long been understood to have turned his attention to this subject; he has in the instance of the engraving before us, exhibited his zeal; his qualifications are generally acknowledged, and he could not, therefore, do a greater service than to execute this long expected task. Among the works to which the reader may refer, are Wren's Parentalia, Elmes' Life of Wren, Godwin and Britton's Churches of London, Britton and Pugin's Public Buildings, London, Ward's Gresham Professors, the Useful Knowledge Life of Wren, Chalmers' Biographical Dictionary, &c. Portraits of Wren are to be found in the Royal Society's Collection, the Sheldonian Theatre, and Salters' Hall, and a bust in All Souls' College, Oxford.

On the 26th of July, 1664, the first stone was laid of the Sheldonian Theatre, at Oxford, (No. 58,) completed 1669, the expense of which, was £12,470 11s. 1d., contributed by the munificent Abp. Sheldon. This is one of the earliest of Wren's works, and the ground plan of it was adopted by him from that of the theatre of Marcellus, at Rome, and so arranged as to receive 4000 persons. The roof, 80 feet by 70, rests upon the side walls without crossbeams, and is one of the first and most admired examples of that practice. In 1800 it was discovered to be in danger of falling, and another roof substituted (for a description and engravings of the roof, see Plot's Oxfordshire, Wren's Parentalia, and Elmes' Wren.)

In 1668, he built the chapel of Pembroke College, Cambridge, at the expense of his uncle Bishop Wren. It is 54 feet long by 24 broad, and 30 feet high. The front is of four Corinthian pilasters.

In 1664, he was employed at Oxford in rebuilding Trinity College. A new court of three sides is among these works, the north side of which was completed in 1667, the west side in 1682, and the south side in 1728. The first stone of the chapel (No. 59), was laid on the 9th July, 1691, and the shell completed at the expense of £2000, contributed by Dr. Bathurst. It is of the Corinthian order.

In 1665, he was called upon to furnish designs for the magnificent Library of Trinity College, Cambridge, (No. 61,) which cost £20,000, and is 200 feet long, 40 feet broad, and 38 high, interior measurement. It has two fronts.

In 1668, he was again employed by Archbishop Sancroft, to build a chapel for Emanuel College, Cambridge. This chapel, including the ante-chapel, is 84 feet long, 30 broad, and 27 high; the floor of marble, and the ceiling richly ornamented in stucco. It was finished in 1677.

In 1668, Wren built the old Custom House, (No. 47,) which was burned down in 1718, being the only one of his buildings, as Elmes remarks, of which, in the course of a long life, he witnessed the destruction, a fortune not always attendant upon architects.

In the same year, he was called upon to report upon the state of the spire of Salisbury Cathedral, which he did in an interesting document.

In 1670, he began Temple Bar, (No. 35,) finished in 1672.

In 1671, he began the Monument, (No. 39,) which was completed in 1677. Its height from the pavement, is 202 feet, (30 feet higher than the column of Antoninus,) and stands on a palladian Pedestal, of 21 feet square, the plinth being 27 feet. The lower diameter of the

shaft is 15 feet, and it contains a staircase of black marble of 345 steps.

In 1670, St. Sepulchre's, opposite Newgate, was rebuilt by Wren, finished 1674; but in 1790, it was again repaired, and much of Wren's work effaced.

The celebrated spire of St. Mary-le-Bow, Cheapside, (No. 38,) was begun in 1671, and completed in 1677-8. It is founded on a Roman pavement, commences from the ground, and rises nearly plain to a height above the houses. The Palladian doric doorways on the north and west sides, are considered good examples of that kind of doorway. The tower has a second story, containing on each side a window between four Corinthian pilasters, and is then surmounted by a block cornice and balustrade, and each angle relieved by a pyramidal group of bold scrolls, supporting a vase. Among these rises a circular stylobate, supporting a temple of the same figure, and of the Corinthian order, the cell of which serves to support the lower part of the spire. From the balustrade of the circular temple proceed a series of carved flying buttresses supporting another Corinthian temple, with four porticos of two columns each. On the summit is an obelisk, supporting a large gilt dragon.* The interior of the church is divided by arcades into a nave and side aisles. Length 65 feet, breadth 62, height 38.

October 16, 1672, the first stone was laid of St. Stephen's, Walbrook, completed in 1679. (No. 23 and 24.) The body of the church is nearly a parallelogram, divided into aisles. Four rows of Corinthian columns form five unequal aisles, the centre being the largest, and those next the walls on either side the smallest. Within one intercolumniation from the east end, two columns from each of the two centre rows are omitted, and the area thus formed, is covered by an enriched cupola, supported on eight arches, which rise from the entablature of the columns. The columns are raised on plinths the same height as the pews. Inner dimensions—length 82 feet 6 inches, width 59 feet 6 inches, height to the flat ceiling of the side aisles 36 feet, and to the top of the dome 63 feet; internal diameter of the dome 45 feet. The dome is formed of timber and lead. Ralph observes that this church is famous all over Europe. Perhaps Italy itself can produce no modern building that can vie with this in taste and proportion.

St. Michael's, Cornhill, (No. 44,) was begun to be rebuilt in 1672, and its tower in 1722. The body of the church is in the Italian style, and is divided into a nave and aisles by Doric columns and arches supporting a plain groined ceiling. The walls of the church do not form right angles with one another, whence Mr. Godwin infers that Wren availed himself of the old foundations. The length of the church is 87 feet, breadth 60, and height 30. The tower is in the perpendicular style, in imitation of that of Magdalen College, Oxford, and rises to the height of 130 feet.

St. Mary-at-Hill, near the Custom House, was rebuilt in 1672. It is 96 feet long, 60 feet broad, and to the centre of the cupola, within the church 38 feet high. At the west end is an ambulatory. Four Italian doric columns placed within the area support an entablature proceeding from pilasters against the side walls so as to produce a cruciform arrangement of the ceiling. The centre space is covered with a cupola.

In 1673, St. Benedict Fink, Threadneedle Street, (No. 54,) was built. The external walls of this church form a decagon, within which six composite columns form a parallel aisle in the centre, and support a small elliptical cupola. The spaces between the columns are arched so as to form a series of recesses round the building, having a singular effect. It is much admired by some of Wren's disciples, but its merits are contested by others. Greater inner diameter 63 feet, lesser 48, height 48. The tower and cupola are now pulled down, and the church is to be refronted as part of the Royal Exchange improvements.

St. Olave, Jewry, begun in 1673, completed in 1676; the length is 78 feet, width 34, height 36. Height of tower to the top of the pinnacles 88 feet. The interior has no architectural claims. It contains the tomb of Alderman Boydell.

St. George, Botolph Lane, (No. 45,) was finished in 1674, and cost £4509 4s. 10d. It is plain and unpretending. The interior is divided by Corinthian columns four on each side, far apart, into a nave and aisles.

St. Dionis Back Church, Lime Street, built 1674, consists of a nave and two aisles, formed by Ionic columns, supporting what Mr. Godwin calls an ugly entablature and arched ceiling.

On the 21st of June, 1675, the first stone of the cathedral of St. Paul (No. 1) was laid, on December 2nd, 1697, the choir was opened for divine service, and in 35 years the whole edifice was completed, under the direction of one architect and during the rule of one bishop of London. Its cost was £747,954 2s. 9d. The ground plan of the church is a Latin cross,* having lateral projections at the west end of the nave, in order to give width and importance to the west front elevation. The exterior is of two orders, the lower Corinthian, and the upper composite, between which are generally semicircular-headed windows in the lower story and decorated niches above, the whole, except at the east and west ends, crowned with a balustrade, which was forced upon Wren, by his brother commissioners, in opposition to his own opinion. The two orders he was compelled to use, contrary to his first design, being unable to procure Portland stone of more than four feet diameter. At the west end, above a lofty flight of steps, is a double portico of coupled Corinthian columns, twelve in number in the lower, and eight in the upper, terminated by a pediment, in the tympanum of which is sculptured the conversion of St. Paul. At the extremities of the front rise two campanile towers, each adorned with a range of Corinthian columns, and covered with a bell-shaped dome, crowned with a pine-apple. On the pediment are colossal statues of the apostles. The projection of the portico is about 1½ diameter, but to ensure depth of shadow, the central portion of the front wall of the cathedral is set back 25 feet from the inner face of the columns. The east end of the cathedral is terminated by an apsis, or semi-circular projection. At the junction formed by the nave and choir with the transepts, rises a cylindrical wall slightly inclining inwards towards the top, and from which springs the magnificent dome with the lantern on the summit, surmounted with a gilded ball and cross. The drum of this dome is surrounded with a peristyle of 32 Corinthian columns, rising from a plain basement. The entablature of the columns supports a gallery round the basement of the dome, adorned with a balustrade. The basement presents a series of 32 pilasters, each over the corresponding columns of the peristyle, with windows between them, and over their entablature; from a plinth of two steps, begins the external sweep of the dome. At its summit is a second balcony or gallery, where the lantern commences. The interior contains a nave and two side aisles, formed throughout by massive piers, dividing them from the nave and choir, and adorned with composite pilasters, from the entablature of which spring semicircular pilasters connecting the piers with each other. On the face of each pier towards the nave and choir is a single Corinthian pilaster, nearly equal in height to the under side of the crown of the arches, supporting an entablature which extends throughout the church. Above the latter is an attic story, from which, at certain intervals, springs a semicircular arch, spanning the body of the church, and over each of the spaces which occur between these, the angles being filled with pendentives, rises a small flat cupola from an enriched cornice. In the central portion of the building, over which rises the cupola, are eight solid piers ornamented with pilasters similar to the others; but the openings of the arches are nearly equal in height to the ceiling of the nave and choir. Above the openings and around the dome extends a bold cornice, forming the floor of the whispering gallery, and bearing an iron railing. The drum of the cupola is adorned with a range of composite pilasters, rising from a plain basement above the gallery, and between which are windows. From the entablature of these pilasters springs the inner dome, and having an opening in the crown in order that it may

* History and Description of St. Paul's Cathedral, by George Godwin, Jun., Esq., M.R.S., M.R.I.B.A. London, 1837.

(Note). See engravings in the *Journal*, Vol. III. pp. 329 and 330, and Vol. IV. p. 375.

* See an engraving in the 3rd vol. of this *Journal*, p. 329.

receive lights from the lantern above. The inner part of the dome is decorated with paintings by Sir James Thornhill, although Wren wished mosaic to have been employed. The dome of the Pantheon it is observed,* is no higher within than its diameter; the dome of St. Peter's is two diameters, the one appears too high and the other too low, Wren has taken the mean, showing a concave every way, and lighted by the windows of the upper order. Above the inner dome again, in order to carry the lantern with which the cathedral is adorned, (said to weigh 700 tons,) Wren has introduced a brick cone, two bricks thick, and having every five feet high a course of bricks eighteen inches long, bonding it throughout the entire thickness; and on which is constructed the exterior of the dome, which is chiefly of wood. A want of ornament is observable in the interior, and those introduced are not in good taste, favouring too much of Sir Christopher's studies at Paris. Beneath the whole cathedral is a crypt.

We may observe here, that some doubt may be expressed as to James II. having interfered to alter the original plan, for in that plan the circular walk round the centre provided amply for processions and the pomp of worship.

The following are the comparative dimensions of St. Peter's and St. Paul's.

	St. Peter's. feet.	St. Paul's. feet.
Length of church and porch	729†	500
Length within	669	500
Breadth within the doors of the porticos	510	240
Breadth at the entrance	226	100
Breadth of the front without	395	180
Breadth at the cross	442	223
External diameter of the cupola	199	145
Inner ditto	139	108
Height from the ground without to to the top of the cross	{ 437 } { 432 }	{ 340 } { 330 }
Height of the church	146	110
Height of columns in front	91	40

In 1675 the Royal Observatory at Greenwich (No. 40) was begun on the site of an ancient tower, and in 1676 it was finished.

In 1675, St. Michael's, Wood Street, (No. 14,) was rebuilt. Its interior forms a large and well lighted parallelogram, with an ornamented coved ceiling. The exterior of the east end presents four Ionic pilasters on a stylobate, supporting an entablature or basement, and having three circular-headed windows in the intercolumniations. Length within 63 feet, breadth 42, height 31. Height of tower, 90 feet.

In 1676, Wren built St. Stephen's, Coleman Street, the interior of which presents nothing remarkable. The length of the church is 75 feet, breadth 35 feet, height 24 feet. Height of tower, 65 feet.

St. Magnus the Martyr, London Bridge, (No. 12,) was built in 1676, and the steeple in 1705. On the top of the square tower, is introduced an octagon lantern, crowned with a cupola and short spire. The interior is divided into a nave and aisles by Ionic columns. The ceiling is cambered. The interior is 90 feet long, 59 broad, and 41 high.

St. Michael's, Bassishaw, was begun in 1676, and finished in 1679, and is a plain, substantial building. The inner dimensions are 70 feet long, 50 feet broad, and 42 feet high. The interior is divided by Corinthian columns into two aisles.

St. Mildred's, Poultry, was built 1676, and presents nothing remarkable in its interior. It cost £4564 9s. 7½d. Its length is 56 feet, width 42 feet, and height 36 feet. The height of the tower is 75 feet.

St. James's, Garlickhithe, (No. 57,) was begun in 1676 and finished in 1683. The interior consists of a nave and side aisles, formed by Ionic columns on high plinths. The length of the church is 75 feet, breadth

45, and height 40. The height of the tower, 98 feet. The cost of the church was £5357 12s. 10d.

St. Nicholas Cole Abbey, (No. 31,) Fish Street Hill, was built in 1677. The interior is well proportioned, with Corinthian pilasters against the walls, and the ceiling divided into panels. The interior length is 63 feet, width 43 feet, and height 36 feet. The height of the steeple is 135 feet.

St. Mildred's, Bread Street, was rebuilt between 1677 and 1683. The interior is remarkable as being entirely covered with a large and highly enriched cupola or dome, formed within the external roof by means of slight deal ribs attached to the principal timbers, and lathed and plastered. The length is 62 feet, breadth 36 feet, and height 40 feet.

In 1677, was built St. Mary, Aldermanbury. It is 72 feet long 45 feet broad, and 38 feet high; divided into a nave and aisles, by composite columns, presenting six intercolumniations, and bearing an entablature. The ceiling of the nave is wagon-headed.

St. Michael's, Queenhithe, (Nos. 16 and 25,) was built in 1677, and is 71 feet long, 40 feet broad, 39 feet high, and the tower and spire 135 feet high.

St. Bride's, Fleet Street, (No. 3,) was built in 1680, and cost £11,430. The steeple was completed in 1703, (the first stone having been laid in 1701.) It is 226 feet high. The two lower stories of the spire, which rises from a grand tower, are Tuscan, the third Ionic, and the fourth composite. From this latter springs the tower. The exterior of the east end of the church is neat, and the dressings of the great window in a bold style. The interior of the church is approached by a porch within the tower, and a vestibule beneath the organ gallery. An arcade of coupled Tuscan columns on either side divides the area into nave and aisles. The ceiling is arched. The recess at the east end forming the chancel, is richly decorated. The inner length of the church is 99 feet, breadth 58 feet, and height to the crown of the arch 48 feet 6 inches.*

St. Swithin's, London Stone, was built in 1680. The ceiling of the church is formed into an octagon cupola, springing from half columns against the walls, and one whole column before the organ gallery. The church is 61 feet long, 42 wide, and 40 high. Tower and spire 150 feet high.

In 1680, Wren began, and in 1682 finished, the church of St. Clement Danes in the Strand. He contributed his exertions to this building gratuitously. The interior, richly decorated, has a cambered roof, supported with Corinthian columns. The south front of the building has a circular portico of six Ionic columns. The dimensions are, length 96 feet, breadth 63 feet, height 48 feet. The height of the tower is about 116 feet.

St. Anne and St. Agnes, Aldersgate Street, was also built in 1680. The interior, 53 feet by 53 feet, and 35 feet high, is divided into a large square in the centre by four Corinthian columns.

St. Mary Aldermay, Bow Lane, (No. 37,) is in the florid style, and is supposed to be a copy of the old building. It cost £5000, contributed by Henry Rogers, Esq. The interior consists of a nave, two aisles, and a chancel. The bell tower is divided by string courses into four stories, and terminates with an open parapet; the octagon turrets at the four angles are panelled to the whole height, and surmounted with carved finials. The length of the church is 100 feet, breadth 63 feet, height 43 feet. The tower is 27 feet square, and 135 feet high. It was built in 1681.

St. Antholine, Watling Street, (No. 41,) was built in 1682, at an expense of £5700. The interior is covered with an oval shaped dome, worthy of observation. The length of the church is 66 feet, breadth 54 feet, and height 44 feet. The steeple is 154 feet high.

St. Augustine's, Watling Street, (No. 5,) was built in 1682, and finished the 23rd Sept., 1683; the steeple in 1695. The interior is small, divided into a nave and aisles by Ionic columns, bearing a wagon-headed ceiling. The dimensions of the church are 51 feet long, 45 broad, and 30 high.

Chelsea Hospital (No. 48) was begun in 1682, and finished in 1690.

* Library of Useful Knowledge, Life of Wren.
† See Mr. Godwin's note on this, p. 47.

* See an Engraving in the Journal, vol. 3, p. 329.

It cost £150,000. The principal building consists of a large quadrangle of brick, open on the south side. The east and west wings are each 365 feet in length, measured from the north front. In the centre of the front and each of the wings are pediments of free stone, supported by doric columns. The internal centre is occupied by a vestibule, terminating in a dome, and the whole length of the principal building, from east to west, is 790 feet.

In 1683, Wren was employed to build a palace at Winchester, for the bishop, but a great part of it has since been pulled down.

He was also employed to build a palace in the same city for Charles II., (No. 20,) the foundation stone of which was laid on the 23rd March, 1683, by that monarch. This building was never completed, and the remains are now converted into a barrack. The design for the original palace, is to be found in Milner's Winchester, vol. 1, p. 433.

In 1683, the Ashmolean Museum, at Oxford, was built.

St. Clement's, Eastcheap, was begun in 1683, and finished in 1686. Its interior is a parallelogram, with an aisle on the south side, separated from the body of the church, by two columns, of the composite order, rising from very high plinths. The length is 64 feet, breadth 40, height 34. The height of the tower is 88 feet.

In 1683, Wren built the Chapel of Queen's College, Oxford, which is 100 feet long, and 30 broad. The design of the quadrangle, built by Hawksmoor, is also attributed to Wren. Hawksmoor was the pupil of Wren, and his successor as Surveyor for building the fifty new churches under Queen Anne's act. Wren also built at Oxford, the towers and other buildings at All Souls' College, in the pointed style, (Nos. 7 and 8,) and the octagonal bell-tower of Christ Church College, (No. 50,) which is also in the later pointed style, with a lantern and dome, lighted by eight windows.

St. Bennet's Paul's Wharf, (No. 28,) said to be the burial place of Inigo Jones, was rebuilt in 1683. The interior, which is unimportant, is 87 ft. long, 60 feet broad, and 30 feet high.

All-Hallows the Great, Thames Street, was built in 1683. It is remarkable for a carved oak screen. The length of the church is 87 feet, breadth 60 feet, and height 33 feet. The height of the tower is 86 feet.

St. James's, Westminster, (No. 27,) was built in 1683. The exterior, of brick, is plain. In the interior Wren made some exertion; the roof is arched, supported by twelve Corinthian columns, and the ceiling panelled and decorated. The length of the building is 84 feet, breadth 63 feet, height 42 feet. The height of the steeple 149 feet.

The gate of the Temple in Fleet Street was built by Wren in 1684.

St. Martin's, Ludgate, was built in 1684. The tower rises from the ground in the centre of the front, and is surmounted with a spire. The length of the church is 57 feet, breadth 66 feet, height 59 feet. The height of the steeple is 168 feet. The cost of the church, £3378 18s. 8d.; the interior is formed into a Greek cross by four composite columns, standing on high plinths.

All Hallows', Bread-street (No. 15) is called of the Tuscan order. It is of stone, and was built in 1684, and the steeple in 1697. The length of the church is 72 feet, breadth 35 feet, and height 30 feet. The tower, 86 feet high, is of stone, built square, and decorated; the keystones over the windows being carved heads, and between each a large festoon.

St. Mary Magdalen's, Old Fish Street, was built in 1685. It is a substantial fabric, with a bell-tower at the north-west corner. The south-east and east ends display a series of circular-headed windows, with trusses supporting a continued cornice above. The length of the church is 60 feet, width 48 feet, height 30 feet. The cost was £4291. 12s. 9d.

St. Benet's, Gracechurch Street, (No. 9,) was built in 1685. It is 60 feet long, 30 feet wide, and 32 feet high. The height of the tower and spire is 149 feet. The cost of the building was £3563 9s. 5d.

St. Matthew's, Friday Street, (No. 56,) was built in 1685. The east end presents a series of six circular-headed windows on a lofty stylobate, surmounted with a cornice and balustrade. The interior, 60

feet long, 33 feet broad, and 33 ft. high, is plain with a flat ceiling. The height of the tower is 74 feet. The cost of the building was £2381 8s. 2d.

St. Alban's, Wood Street, (No. 42,) in the later pointed style, was built in 1685, and is a bad restoration of the old building. The length of the church is 66 feet, breadth 59 feet, height 33 feet, and height of the tower 32 feet.

St. Mary's, Abchurch Lane, was rebuilt in 1686. The interior is 65 feet long, 60 feet wide, and 51 feet high, covered with a large and handsome cupola, supported on a modillion cornice, and decorated with paintings by Sir James Thornhill. The height of the tower and spire is 140 ft.

St. Andrews', Holborn (No. 43) was built in 1686. The interior is large. It is divided into a nave and side aisles by pillars carrying a wagon-headed ceiling. The length is 105 feet, breadth 63 feet, and height 43 feet. The height of the tower is 110 feet.

In 1687, Christ Church, Newgate Street, (No. 6,) was begun, and finished in 1704. The interior is divided into a nave and side aisles by small Corinthian columns, supporting a wagon-headed ceiling. The length is 114 feet, breadth 81 feet, and height 38 feet. The height of the steeple is 153 feet. It is a pleasing object at a distance, but is a confused composition, although its parts are well proportioned.

St. Lawrence, Jewry (No. 22), the corner of Cateaton-street, was begun 12th April, 1671, and finished 1686. The interior consists of one large area, with an aisle on the north side, formed by Corinthian columns carrying an enriched entablature, standing on a plinth, and supporting a pediment, the inter-columniation being occupied by two windows and a niche. The extreme angles of the front are terminated by pilasters, between which and the columns are other niches. The steeple is 130 feet high.

St. Margaret Pattens, Fenchurch-street (No. 36), built in 1687, consists of a nave and aisle, and chancel. The walls are decorated with Corinthian pilasters. The ceiling is flat, having a square of fretwork, and the arches similarly adorned. The length of the church is 66 feet, breadth 52 feet, height 32, and of the tower and spire 198 feet 2 inches.

St. Margaret's, Lothbury (No. 49), was erected in 1690. Consists of a nave, and decorated with Corinthian pilasters, and an aisle formed by two columns of the same order. The ceiling is coved. The length is 66 feet, breadth 54 feet, and height 36 feet. The tower and spire 140 feet high.

The church of St. Edmund the King, Lombard-street (No. 51), was also built in 1690. In it was buried, in 1563, Edward Shute, author of a folio called "The First and Chief Grounds of Architecture," being one of the first English works on practical architecture. The interior of the church is plain, surmounted with a dome or skylight, but it is well fitted up. The length is 60 feet, width 39 feet, height 33 feet. The height of the tower and spire, which are much ornamented in an incongruous manner, is 90 feet.

St. Andrews of the Wardrobe was built in 1672. The interior is divided by 12 square Tuscan pillars, in two stories, into a nave and aisles, surmounted with a cambered ceiling, formed into panels. The length is 79 feet, breadth 59 feet, and the height 38 feet. The interior is plain. The height of the tower is 86 feet. The cost of the building was £7060 16s. 11d.

In 1690, the College of Physicians, Newgate-street (No. 52), was finished. It is now converted into a meat market, and the upper part of the theatre into a brass foundry. The anatomical theatre, lighted by a lantern, was well designed for both seeing and hearing.

In 1692 Wren built Morden College at Blackheath (No. 46). It is of brick, with stone quoins and cornices, forming a quadrangle, surmounted with a colonnade. In the interior is a chapel.

In 1694, All Hallows', Lombard-street, was built. The interior is fine, being subdivided, and is 84 feet long, 52 feet broad, and 30 feet high. The tower is 85 feet high, and with the rest of the exterior is quite plain.

St. Mary, Somerset, Thames-street (No. 60), was erected in 1695.

The interior has a flat ceiling, and is divided into a nave and two side aisles, is quite plain. It is 83 feet long, 36 feet broad, and 30 feet high. The tower is square, with barbarous pinnacles, the height to the top of them being 120 feet.

St. Michael's Paternoster Royal, Thames-street (No. 33), was built in 1694, and the spire in 1713. The interior is plain, with a flat ceiling coved at the walls. The length is 86 feet, breadth 48 feet, and height 40 feet. From the tower rises a pleasing tower of two orders, the lower story, Ionic, bearing an entablature and vases. The whole height is 90 feet.

His patroness, Queen Mary II., having died, Wren was employed by William in 1695, to design the mausoleum in Westminster Abbey.

Wren was employed by Queen Mary II. to enlarge the Royal Palace at Greenwich (No. 19), which was subsequently converted into the Marine Hospital. The principal front to the Thames contains the Royal Court, 300 feet square, having on the west the courts of King Charles II. and King William, and on the east that of Queen Anne and Queen Mary, and on the south the great hall and chapel. The court of King Charles II., containing the great end wing, is of Portland stone, and of the Corinthian order. In the middle is a tetrastyle portico, with arcades. At each end is a great pavilion, rising into an attic order, and forming a high tower. The other wing corresponds. The Royal Court contains two colonnades being each 30 feet long, and consisting of 150 columns and pilasters 20 feet high. The great hall in King William's building is 106 feet long, 56 feet wide, and 50 feet high. The painting of it cost £6,685.

St. Vedast, Foster-lane (No. 5), was begun in 1694, and finished in 1698. The interior is divided into a nave and aisle by a range of Tuscan columns. The ceiling is flat, and formed into one large panel, enclosing others smaller, and decorated with wreaths of fruit and flowers. The length is 69 feet, breadth 51 feet, height 36 feet. The spire and the top of the square tower are by some admired. It consists of three stories, the lowest presenting four concave faces, with clustered pilasters and piers at the angles. The centre story has four convex stories, with plainer piers; and the third story consists of an obelisk, with scrolls at the corners of the base.

St. Dunstan's in the East (No. 12), was restored by Wren in the pointed style; and in 1698 he built the tower and spire, which are on the plan of the spire of St. Nicholas at Newcastle. The spire is supported on a tower 20 feet wide, by four flying arches. Wren's nave has since been pulled down and rebuilt.

He also repaired the interior of Guildhall.

A theatre built by Wren near Fleet-street, shortly after the restoration, stood upon the site formerly occupied by the New River Company's offices.

At St. James's Palace Wren was also employed. He designed the Doric court, the council chamber, the audience-room, and the dining-room.

Buckingham House, now pulled down was built in 1703 (No. 29).

Marlborough House (No. 17) was begun in 1709.

In 1713, Sir Christopher was employed to repair Westminster Abbey, when among other works he extended the west front (No. 4), and carried the towers up to the height of 225 feet. The design is incongruous, and is far from a happy specimen of his skill in the pointed style.

Mercer's Hall, Cheapside, contains a fine set of rooms and a chapel.

Isleworth church is partly built on a plan designed by Wren.

The new buildings at Hampton Court Palace (No. 30 and 32) were built by Wren in 1690. What are called the king's apartments are 328 feet long, and the queen's apartments, 330.

The house in Cheapside occupied by Mr. Tegg was the Old Mansion House, built by Wren (No. 55.)

On the south side of Queen-square, Bloomsbury, was a house built for the Earl of Newcastle.

Near the south-west angle of St. Paul's church-yard is another of his mansions.

Another was in Great Russell-street, Bloomsbury, and also some buildings in Lawrence Pountney Hill (No. 25).

At Chichester, where he very ingeniously repaired the spire of the cathedral (No. 2), are two houses of red brick, with stone architraves, and a Corinthian modillion cornice.

A hunting-palace at Newmarket built for Charles II., was also among his designs.

The entrance and other buildings in Doctors' Commons (No. 34 and 62) is another work.

The counting-house and court-room in Christ's Hospital (No. 10), were built by Command of Charles II.

At Windsor Castle Sir Christopher built the Star Building about 120 feet long, now the Stuart Building. In 1676 he enlarged the North Terrace, and executed other works. A design for an Italian palace is inserted in Wyatville's Illustrations of Windsor Castle.

He was also employed on the repairs of the Tower and other public buildings, and in erecting a number of buildings in the city. It may be further observed that most of his churches are enriched with altar pieces, and carved pulpits and fonts executed under his direction.

DR. PAYERNE AND HIS DIVING-BELL EXPERIMENTS.

AN announcement was lately sent forth, with a loud flourish of trumpets, that a discovery had been made of vast importance in all sub-aqueous works, by which man would be enabled to surpass the fishes in their natural element, and to live for an indefinite time without communication with the atmosphere. Dr. Payerne, the alleged discoverer of the new process for decomposing water in quantities sufficient to support animal life by the resulting oxygen, exhibited his prowess in the diving bell at the Polytechnic Institution to the wondering company; and in the presence of several scientific men, remained under water, without any supply of air beyond the contents of the bell, upwards of three hours. The Doctor took down with him a bag, supposed to contain the mysterious apparatus by which he was enabled to generate air for the support of life so long under water, and having accomplished this feat, he was looked upon by the admiring crowd as a water deity, and the newspapers failed not to predict the most important consequences from the discoveries of this modern Neptune. The experiment having been several times repeated in the diving bell of the Polytechnic Institution, it was determined to bring Dr. Payerne's discovery to the test of practical utility in the operations on the wreck of the Royal George at Spithead. Major General Pasley had promised to afford the opportunity; accordingly, on the 2nd ult. the experiment was made, and was subsequently repeated, during which six descents were attempted with various results. A very ample report of the experiments was given in the *Times*, and in a manner which led to the belief that the account was from authority, and had been furnished by some person who took part in the proceedings. The report is too long to copy entire; we must, therefore, be satisfied with a summary of the two days' adventures at Spithead, culling here and there, from the original, passages which evidently show, notwithstanding the care taken to produce an opposite impression, the failure of Dr. Payerne's mysterious apparatus to afford facilities in submarine undertakings, so far at least as these experiments may be considered the test of its value.

In the introductory allusion to Dr. Payerne's previous experiments, it is stated that Major General Pasley, after having witnessed the Doctor's "performances" at the Polytechnic Institution, still entertained great doubts whether the apparatus would be equally efficient at Spithead; "for, "as he told the Doctor," though he was satisfied that he could produce good air at any depth, the pressure of from 12 to 15 fathoms of water at the bottom of the anchorage at Spithead would compress the air in a diving bell so much, that though men might exist in it, they would not be able to work to advantage, being nearly up to their necks in water."

We must suppose that the reporter is here in error, for he represents General Pasley to be egregiously ignorant of the commonest law of pneumatics, and of notorious facts connected with the use of the

diving bell. The General must surely have known that if Dr. Payerne could generate any gas with his apparatus, it must become, at the instant of its generation, of the same pressure as the air in the bell, and, to the extent of its volume, expel the water as effectually as air pumped in, or otherwise introduced, under any state of compression. The difficulty which is represented to have been raised by General Pasley was, however, a lucky means of relieving the Doctor from an awkward predicament into which he would otherwise have been placed as soon as the bell was lowered into deep water. The thought suggested itself, that General Pasley's objection might be removed by attaching to the bells *cylinders of highly compressed air*. These cylinders were four in number. Each one was of the capacity of four cubic feet, and the air was compressed to ten atmospheres. The Doctor consequently was provided with an available supply of air, independently of the contents of the bell—and also independently of the "good air" generated in the mysterious box—equal to 160 cubic feet at the pressure of the atmosphere. Notwithstanding this ample provision, General Pasley still had misgivings of the result, the reporter informs us:

"When the preparations were completed, Dr. Payerne took his seat in the diving bell accompanied by Major-General Pasley, *who, having full confidence in the goodness of the Doctor's air, but less in his expedient for keeping out the water from the bottom of the bell, took the precaution of putting on a water-tight diving dress*, offering another to the Doctor, who rejected it, in the belief that he would be able to keep the bell completely dry. *They had, however, scarcely descended more than 10 or 12 feet below the surface, when the water came in upon them so fast that the Doctor requested that the bell should be hauled up out of the water, as he said he was sure that it must be leaky.*"

The fact was as Dr. Payerne suspected. The air escaped from the top of the bell, in consequence of the cap over the air hole not having been screwed down tight. During this first attempt to descend, one of the cylinders of compressed air was exhausted, though the bell had been lowered only twelve feet. It does not appear whether or not Dr. Payerne attempted to use his air-generating apparatus in this experiment. His confidence in his resources was, however, so much shaken by this first adventure, that, before going down a second time, he followed General Pasley's prudent example, and put on a diving dress.

In the second descent they were lowered 12½ fathoms, "*when they were hauled up by mistake of a signal before they had quite reached the bottom.*" The three remaining cylinders of compressed air were exhausted in this descent; the effect of it was so far successful that it kept the water within six inches of the bottom of the bell. Dr. Payerne's assistant and Lieut. Hutchinson next descended, but as they would not wait to have the cylinders refilled, "they were obliged to make the signal to stop lowering after they had only descended 23 ft. the bell being at that time nearly half full of water." Thus the experiments of the first day ended without any result. It does not appear, indeed, that Dr. Payerne or his assistant on these occasions once employed the air-generating apparatus; or if they did, it was certainly of little use.

On the second day, as on the first, there were three descents; two by General Pasley and Doctor Payerne, and one by the Doctor's assistant and Lieutenant Hutchinson. As these were the most important trials, we will give the account of them in the reporters' words:—

"Dr. Payerne and Major-General Pasley went down twice—first to the depth of 12½ fathoms, when they were pulled up by mistake of a signal before they reached the bottom, to their great disappointment. After the four cylinders were filled again with compressed air, which was done in about an hour, they descended a second time, and as the men above had strict orders not to stop lowering until the diving bell reached the bottom, and not to haul it up again, unless they pulled the signal line three or four times, Dr. Payerne had the satisfaction of getting a small piece of wood from the wreck of the Royal George, after which they made the signal to ascend. Another experiment, of still greater interest, was tried at the suggestion of Lieutenant Hutchinson, who went down without any air cylinders, accompanied by Mr.

Hardiman, having the end of one of the diver's air-pipes with them, through which air was forced into the bottom of the diving-bell by one of the small pumps which usually supplies air for a helmet-diver. By means of this pump the water was expelled from the lower part of the diving-bell, and replaced by condensed air, which enabled them to descend to the very bottom, there being no cylinders to prevent the bell from taking the ground, as in the former experiment; and Mr. Hardiman also brought up some small relics from the wreck.

"The result of these experiments is, that both Major-General Pasley and Lieutenant Hutchinson expressed their high opinion of the merit of Dr. Payerne's invention, as applied to the diving-bell; for they considered that the air they breathed in the bell was perfectly good; and the whole apparatus for purifying it was contained in a case not larger than a common portable writing-desk, which gives no trouble but that of turning a small winch or handle occasionally, and as, besides water, two very cheap and simple ingredients only are used, the manipulation requires no science on the part of the person in charge; and, when the diving-bell is once filled with compressed air, either by letting it escape from vessels previously filled with it, as in the first experiment, or by four men pumping for less than half hour, as in the second experiment, no more pumping is necessary, as the air in the bell never requires to be changed."

After carefully perusing the detailed accounts of Dr. Payerne's operations under water, we entertain a very different opinion of the merit of his invention from that which is stated to have been expressed by General Pasley and Lieutenant Hutchinson. We shall now proceed to state the reasons which induce us to look sceptically on the Doctor's apparatus, and to show, from well known facts, that whatever may be its capabilities for generating vital air, he has hitherto effected nothing with it which might not have been accomplished without any apparatus whatever, or by means that have been long known.

It has been ascertained that one gallon of air will support the life of man, when the same air is inspired and expired, about one minute. In a diving-bell which contained 60 gallons of air, a man should therefore be able to support life under water, without any additional supply of air for one hour. The capacity of the diving-bell at the Polytechnic Institution, which will hold six persons, is about 140 cubic feet; which is equal to 870 gallons. This quantity of air ought therefore to sustain the life of one man for fourteen hours. The effect of breathing vitiated air for so long a time would, however, be most probably very injurious, consequently though a person introduced in such air might continue to live for some time, it might not be capable of continuing to sustain the life of one who had been for hours enduring a gradually vitiating air. But we may safely assume that a man with a supply of 140 cubic feet of air might continue under water without much inconvenience for at least four hours. Here then we have a sufficient solution of Dr. Payerne's mystery, without seeking to extract the secrets of the "box." Whatever latent virtue it may contain, it is clear that the Doctor might have managed well enough without its development in the diving-bell of the Polytechnic Institution, where he remained under water in his most successful experiments, three hours and a half. That he did not accomplish more than could be effected by others was afterwards proved most conclusively. Two persons, subsequently to the Doctor's experiments, determined to try how long they could remain in the bell without additional supply of air; and without the aid of any box or any apparatus whatever, they remained under water for *an hour and a half*, during a great part of which time they *burned a light*. The consumption of oxygen gas by two persons and a burning candle for one hour and a half, must have been at least equal to Dr. Payerne's single consumption for three hours and a half. It is clear, therefore, that whatever advantage he might have derived from the superior purity of the air (if any) manufactured by his apparatus, he did not with its aid, and though he had greater inducement to suffer inconvenience, remain longer under water than any other person might have done.

Of the experiments at Spithead, viewed as a test of Dr.

Payerne's invention, little need be said. They were, with one exception, decided failures; and even in the experiment which was most successful, the whole achievement consisted in bringing up a small piece of the wreck of the Royal George, to prove the divers had actually reached the bottom. This was the mighty result of the new discovery which, as announced, was to enable man to dwell with ease at the bottom of the ocean, and to inhale water for air!

Let us examine the means by which this feat was accomplished, to see whether, trifling as it was, any part of it can be reasonably assigned to the operations of Dr. Payerne's box and materials. We are not informed of the size of the bell employed by General Pasley, but from the circumstance of its being constructed of wrought iron, and made expressly to carry on the operations against the wreck of the Royal George, we must conclude that it was at least of the size of those formerly employed by Dr. Halley and Mr. Smeaton, which contained 60 cubic feet of air. The cylinders of compressed air, we have already stated, would furnish a further supply of 160 cubic feet of the pressure of the atmosphere. The two divers would, therefore, have a supply of air equal to 220 cubic feet. With this supply they might have remained under water, if consuming but one gallon per minute, for ten hours; but estimating the quantity of air requisite to sustain life without much inconvenience, from actual experiment at the Polytechnic Institution, we will take it at two hours and a half.

How long they did remain below each time, the reporter fails to state, but it would appear that the bell was drawn up nearly as soon as it reached the bottom; therefore, we may presume the longest experiment did not last more than half an hour. Consequently there could not have been occasion for the Doctor to have generated more air than the supply he took down; and however simple and easy the manipulation of the apparatus may be, he might have saved himself the trouble of turning the handle of the box. Another question arises, if the Doctor did generate any gas *what became of it?* It is known that the volume of air expired from the lungs is very nearly equal to the quantity inspired, and we find that even with the whole supply of air from the cylinders, the water was still six inches within the bell. This could not have been, had any quantity of gas been generated, for it must have expelled all the water and forced itself out of the bell.

The *naïveté* with which the authorised reporter records the success of the last experiment at Spithead, is extremely amusing. Lieutenant Hutchinson and Dr. Payerne's assistant descended *with an air-pipe supplied by a small air-pump*, and with this they appear to have been more successful than was Dr. Payerne with his cylinders of compressed air, and his mysterious box. This mode of descending in the diving bell, which is called in the report "an experiment of still greater interest" than any previously attempted, it will be at once perceived is the plan first adopted by Smeaton, and since generally adopted; the only variation being that the pipe was smaller, and was taken down in the bell instead of being inserted in the top. It thus appears to be admitted, that so far as the experiments extended, the old plan is more advantageous and much less troublesome than the new invention, which was so extravagantly puffed.

As Dr. Payerne does not disclose the process by which he professes to be able to decompose water in sufficient quantities to supply oxygen gas for respiration, it would be useless to speculate on the practicability, if any such plan were applied to works under water. So far as his experiments have gone, they have, we conceive, proved nothing. The Doctor exhibits a mysterious box; he professes to have in it two simple and cheap materials, which are sufficient to generate air sufficient to support life for an indefinite time; he tries its powers, and the effects produced are no greater than if the box and materials had no existence. Were we to speculate respecting the contents of such a box we might imagine it to contain highly compressed oxygen gas. Fifteen cubic feet of gas might be compressed into a case the size of a portable writing desk; and as one cubic foot of oxygen would support life nearly five times as long as atmospheric air, he would thus carry under his arm a supply equal to 75 cubic feet of common air. This speculation, however, can

scarcely be correct, or the Doctor's mysterious box would have been more efficacious than it proved.

Though Dr. Payerne's experiments have, we consider, entirely failed to show that he possesses any peculiar art of transmuting water into air, they have been productive of advantages by proving that operations under water may be conducted with a much smaller supply of air than has hitherto been considered necessary.

The great publicity which Dr. Payerne has succeeded in giving to his claims to be the discoverer of an important scientific principle, challenges examination, and has induced us to bestow this notice on his experiments. It would be presumptuous to assert that the Doctor has made no such discovery, but if he have, he has been most unfortunate in his mode of announcing it to the world; for whilst claiming to be a philosopher, he assumes the garb of a charlatan.

FIRE-PROOF BUILDINGS.

SIR—The constant danger and frequent loss to merchants, solicitors, and others, through the destruction by fire of the papers and documents entrusted to their care, has induced my clients to erect an extensive range of "fire-proof" chambers and offices in the Old Jewry, City. At this time some description of the method adopted, viz. of omitting timber, and of using cast iron girders and brick arches to carry the floors, whereby each room becomes in a manner an arched vault, may not be unacceptable to your readers, although the idea is not new, the more especially as many professional men, engaged, as they stated, on somewhat similar works, have inspected the buildings and sketched the details, for the purpose of obtaining information respecting the construction.

Fig. 1. Elevation of iron Girder.

Fig. 2. Looking upwards.

Fig. 3. Section of Girder and Arches.

The walls are built without any bond plates, instead of which, in the height of each story, according to the height of it, 5 or 6 courses of wrought iron hooping $1\frac{1}{4} \times \frac{1}{2}$ in. is laid in the walls; it must be laid quite flat, and well lapped together or bound round a brick at the joinings and passings. The hooping was tarred and sanded for better adhesion to the mortar, and kept in about an inch from the face of the wall, as the rust would otherwise stain the plastering.

The girders were of various lengths, from 11 ft. up to 18 ft. 6 in. clear bearing; they rested 9 in. at each end on 4 in. York templates, and were placed 7 ft. apart from centre to centre. The girders ex-

plained by the diagram were for 15 feet bearings, 12 in. deep in the centre, and 8 in. at the ends, and $1\frac{1}{2}$ in. thick in the centre; the forked or divided parts were each $\frac{1}{4}$ thick, and the roll at the top $2\frac{1}{2}$ in. diameter. They were proved to 26 tons by 13 tons in the centre, although there is not a probability of their having to carry 9 tons, but the object was to give confidence to the public; the deflexion was an inch. The skew-backs were cast hollow, having stiffening pieces about 3 ft. apart, as shown by the plan and section.

Between the girders arches were turned in half a brick in cement, care being taken in setting out the work to bring in the courses with very close joints, and so as for the bricks to touch each other at the lower side; the 5 or 6 centre courses were put in without cement, so as to get jammed in tight, after which they were grouted. The rise of the arch was 5 inches, the spandrels were not filled in, and the bricks were well soaked in water.

The centreing was in all cases held up or suspended to the girders by iron hangers, whereby the weight was gradually placed upon it; this would not have been the case if the centreing had been put up on props and afterwards struck in the common way.

About 22,000 feet of these arches have been turned, and not the slightest appearance of a settlement is to be found in any part of them. The floors over the arches are formed in the usual manner, with joists and sleepers. The intrados are plastered, and a soffit with papier maché work is fixed to the underside of the girders to conceal them.

The reliance to be placed on this method of building as a security against the extension of fire from room to room, has been fully tested in the following manner; a large coke fire was made in the centre of each room on the basement floor (which is only 8 feet high) in order to dry the plastering, &c., and although the heat was kept up intensely strong on many successive days, yet it had no worse effect than to make the floor boards, in only two cases out of eighteen, of the rooms over, swell a little so as to be barely perceptible, and that was evidently caused by the quantity of steam driven through from the wet plastering of the arches and walls below.

36, Guildford Street,
September 2, 1842.

I am, Sir,
Your obedient servant,
CHARLES DYER.

NOTES ON THE CONSTRUCTION OF BRIDGES.

Description of SUNDERLAND IRON BRIDGE, with remarks on its construction, and why it has not been more adopted.

In the "Notes on the Construction of Iron Bridges" in your July number, among other matters noticed, it is contended that no advantage is gained in confining the principal weight of iron in the arch at the bottom, over the equal distribution of the metal in the arch, the spandril filling and roadway bearer, and that the great elasticity of wrought iron renders it inapplicable to the purposes of bridge building. The former remark is fully confirmed, and the latter obviated by a combination of the two materials, as in Sunderland Bridge, a sketch of which accompanies this paper, and which for sake of brevity, and as distinction of its construction, I will name the Vertebrated Bridge, the wrought iron bands being like the spinal chord, and the short portions of the arc of cast iron framework being the bones. When it is considered that in each of these ribs, there is a sectional area of $13\frac{1}{2}$ superficial inches of wrought iron employed, whose power of resistance to compression is within an eighth of being twice as much as cast iron, the utility of this mode of construction over that wholly of cast iron must be self-evident, and moreover, the time since the erection of the bridge under consideration proves its practical durability.*

Should the system of a combination of the two materials be fully carried out, by making the bars of wrought iron radiate from the

crown of the arch so as to fill up the whole of the spandril, as in the case with the filling in of the spandril of Chepstow Bridge (a plate of which is given in Weale's Bridges), I have no doubt of the feasibility of extending an arch of this description to the extent of 500 feet, an extent proposed by Telford for the bridge over the Menai Straits, or of 600 feet, as proposed over the Thames by the same engineer.

Mr. Rennie's experiment on Southwark Bridge (see Journal, vol. 3, 1840, page 133) proves that the dilation and contraction of the metal is no impediment, being in that structure only $\frac{1}{16}$ of an inch for an alteration of temperature of 1° of Fahrenheit, and the whole contraction of iron from a fluid to a solid state being $\frac{1}{16}$ as stated by Mr. Edwards, in his account of the Pont du Carrousel in Journal, for last August, page 279.

I must now return to the subject at the head of the paper, and commence with its history. So early as 1790, Rowland Burdon Esq., conceived the idea of throwing an arch of cast iron over the Wear, at Sunderland, for which purpose an Act of Parliament was obtained in 1792. The foundation stone was laid September 24th, 1793, and the bridge opened August, 1796. The quantity of iron in the structure is 260 tons, of which 46 tons are wrought iron. The novelty of the plan adopted on the suggestion of Mr. Burdon, consisted in retaining, with the use of a metallic material, the usual form and principle of the stone arch, by the subdivision of the iron into blocks, answering to the stone of the common arch. These blocks, Figs. 1 and 2, are of cast iron, 5 feet in depth and 4 inches in thickness; each block has

* The use of wrought iron in connexion with bridgework, is shown in Mr. Brunel's arch, described in Journal, vol. 1, 1838, page 119, which contained no less than 54 pieces of hoop iron, 1 inch broad, by $\frac{1}{8}$ thick, interspersed between the joints.

Fig. 2.

Fig. 1.

three arms, and forms part of a circle, the middle arm is 2 ft. in length, the other two in proportion; on each side of the arms are flat grooves $4\frac{1}{2}$ of an inch deep and 3 in. broad, into which are inserted bars of wrought iron, which connect the blocks with each other; they are secured thereto with square bolts driven through the shoulders and arms of the blocks and the bar iron, and are fastened by cotterels or forelocks.

Fig. 3. Section of Roadway and Ribs.

The blocks are cast in one piece, but their construction is more easily explained by supposing them to be formed of bars, each block will then appear to consist of three horizontal and two vertical bars; the former cross the latter at the extremities and in the centre; there is a perforation left both above and below the centre crossing, and the vertical pieces cross the horizontal ones at a distance of 5 inches inwards from their extremities; another perforation occurs when two blocks are banded together; these perforations diminish the weight of the fabric very much, when compared with a solid arch. Fig. 4, is a perspective view showing two of these blocks united, and also a portion of two of the ribs bolted together with horizontal bolts which also form stays.

Fig. 5.

The whole structure consists of 6 ribs placed 6 feet apart, each containing 105 of these blocks, built on each other, like the voussoir of a stone arch. The abutments are of stone 24 feet thick, 42 feet in breadth at bottom, and 37 feet at top. The span of the arch is

236 feet, with a versed sine or rise of 34 feet. The height to the soffit from low water mark is 100 feet. The spandrels of the arch are filled in with iron circles, diminishing from the abutment to the centre; the superstructure is of timber, planked over, supporting the carriage road, formed of marl, gravel and limestone. The total breadth is 32 feet, with footpaths of flags, and enclosed by an iron pallsade. The whole structure was put together and thrown over the river in the short period of 10 days, without interrupting the navigation, the centre being supported in two places by gearing or frames of woodwork resting upon piles driven into the bed of the river. The whole expense was £26,000, of which £22,000 was subscribed by R. Burdon, Esq., and secured at 5 per cent on the tolls. In the centre of the pallsade on each side is a cast iron panel, with the inscription "*Nil desperandum, auspice deo.*" The bridge is free on entering the town, and $\frac{1}{4}$ d. toll is paid in recrossing or leaving the town.

Mr. Thomas Wilson, of Bishopwearmouth, was the engineer, who was also engineer for a bridge at Staines, on the Thames. Mr. Wilson, in conjunction with Mr. Burdon and Mr. Scarth, took out a patent for this mode of construction, and erected a bridge at Yarm, with less success, as the following account will show. The foundation stone was laid September 3, 1803. The iron was commenced to be laid across September 3, 1804, and the arch completed in 8 days. The arch was cast at the foundry of Messrs. Walker of Rotherham. The form was a circular segment, 180 feet span, 27 feet broad between the pallsades, with a 21 feet carriage road; it was composed of 6 ribs, each containing 39 perforated blocks of cast iron 4 feet deep and 4 inches thick. The whole weight, including pallsades, was 250 tons. The abutments were of stone 30 feet thick, and the flank walls 50 feet long from back of abutments, 7 feet in thickness at base, and diminishing by 6-inch offsets to 4 feet. The height of parapet walls including fascia $4\frac{1}{2}$ feet. The contractors were, Mr. Wheldon for the stonework, amount £2440, and Mr. Wilson, the engineer, for the ironwork, amount £5660. The bridge fell at midnight, January 12, 1806. It had been open for foot passengers some time previous to the falling.

Architects were called in by the magistrates of Yorkshire and Durham to ascertain the cause of the falling, who reported that the internal masonry of the abutment was insufficient to resist the lateral pressure of the arch; they were clearly of opinion that this was the occasion of its fall; a complaint was made to the same effect by the surveyor during the progress of the work. The manner of placing the ribs was not generally approved of, as not being calculated to take an equal bearing or pressure. The old bridge, which had not been pulled down, was then repaired, widened, and substituted for the iron one. These particulars of the Yarm bridge are taken from Grave's History of Cleveland, pub. 1808, page 68, appendix No. 1, and of the Sunderland Bridge, Surtees' History of Durham, vol. 1, page 227, and three plates now very scarce, published at the time of the erection, but I am sorry to say that no letter-press accompanied them. They were engraved by R. Clarke, drawn by J. Raffield and designed by G. T. Wilson. The above untoward event of the falling in of the bridge at Yarm, in my mind, is the reason why this mode of construction has not been more frequently employed, and the distrust of iron as a material for bridge building, as it will be seen that this bridge was built only 21 years after the introduction of iron for bridges. In conclusion, I beg to offer to you, at least, the novel idea of rendering cast iron bridges less brittle by submitting the iron to the process of annealing or to assimilate it by a gradual reduction of its temperature, more to the nature of wrought iron, which appears to me would also increase its capability of resistance to compression. The division of the portions of the arc into short lengths, as the blocks in Sunderland Bridge, has great advantages in providing for the expansion, as when so subdivided it is not so much felt, being divided insensibly among the different joints.

NOTES ON EARTH-WORK.

Account of a Machine called a TIPPLER, used on the Southampton Railway.

To the most casual observer it must be apparent that the limitation of the quantity of earth-work capable of being executed in one day, occurs at the battery or tiphead, and not at the face of the cutting. The excavation being almost unlimited, whereas the width of embankment limits the teaming, the greatest number of men that can be employed at one tip, being from 10 to 12, and the maximum quantity teamed in one day, being 800 wagons, and for the twenty-four hours, 1000 wagons. Side wagons from quitting their load at the side, are much used to facilitate tipping, and the return of the empty wagons from the battery to the excavation. Of the many attempts made to facilitate this operation, one of the first was used on the Carlisle and the Hartlepool railways, by Mr. Grahamsley; and the following testimony will shew the importance in which the attempt was held by the profession. Mr. Vignoles sent a man to the Carlisle line, who reported that it was not worth adopting; Mr. R. Stephenson sent Mr. Copeland and Mr. Noel, contractors, to the Hartlepool line, for the same purpose; both reported it would not answer; Mr. Locke said that if found practicable, it must be for the interest of the contractor to adopt it, finally I believe it was not found to answer. Mr. Buck tried another plan on the London and Birmingham Railway at Watford, viz. projecting balks of timber over the tip, and after the first wagon was teamed, it was pushed forward until a second was tipped, and both returned together; it became useless on new embankment, and was abandoned. The ordinary disposition of temporary roads is generally as follows, viz. two lines of road are laid down called the empty and full line, and where the battery head is approached, the road diverges into branches or spurrings to as many teaming places as the breadth of the embankment will allow: a horse being employed to draw the empty wagons into a siding, until a full set is empty, and to run the full wagons out of the full siding to the tip head. I have not seen any plan of Grahamsley's machine, excepting the account given in evidence on the Southampton Railway in the Appendix to Brees' Railway Practice. The accompanying sketch is made from a rough sketch sent me by a friend who saw the tippler in operation. The frame A

in front, which is perpendicular and supported on two trucks with iron wheels, is provided with a screw B, to raise or lower the cross rail c, to suit the inequalities of the ground. The four balks D are in the direction of the railway; one end of the balks rests upon the brackets E and the cross rail c, the other ends are supported on the embankment already formed; these balks are for supporting the rails of the full and empty roads; the balks D are tied to the brackets F with wrought iron ties jointed; the two transverse balks with rails G are to support a low truck, having rails laid on the top on a level, and in the same direction as the rails of the two roads, the full and empty: so by a side motion the low truck transfers a wagon on the top from one line of rails to the other parallel to it, thereby avoiding the delay of horsing as described above. A very similar arrangement is shown in the Journal, Vol. IV, p. 250, in the description of the Paris and Versailles Railway, for the purpose of saving the expence of a turntable opposite each pair of rails, for transferring the carriages from one line of rails to another. I may also mention that a precisely similar plan is in use at the Nottingham station of the Midland Counties Railway. There being no account published of this machine, perhaps your doing so may elicit further particulars, although there is not much facility given to publish failures.

Yours truly,

St. Anne's, Newcastle-on-Tyne.

O. T.

CANDIDUS'S NOTE-BOOK. FASCICULUS XLI.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. If it was the intention of the architect of the Alliance Office to show how completely an order may be made to lose its character, not by any alteration of, or 'tampering with' its proportions or details, but by perverse and tasteless application of it—he must be allowed to have succeeded admirably. With the Bank immediately facing his own building, he has ventured to make use of the very same order, so introduced, that every point of difference is most decidedly for the worst. Instead of being placed upon a simple stylobate, the columns are raised upon a basement, of such exceedingly poor and ordinary design in itself, that were all the rest perfectly unexceptionable, the lower part of the building would greatly detract from the general effect. As it is, however, the insignificance and anti-classical taste there displayed, is of little consequence, for the upper part of the façade is also poor; therefore, so far, the whole would be tolerably of a piece, where it not that what is of excellent quality in itself, has been dragged in so as to lose its own value, without conferring any on the other parts. That the columns have been forcibly dragged into the design is evident enough, for not only are they introduced without motive, but quite contrary to it; and in such manner, as to occasion glaring and offensive improprieties. It must be confessed, that in the opposite façade of the Bank, columns are employed only for the sake of effect; but then, there they do produce effect—effect of a more than ordinarily picturesque and tasteful kind. There is nothing that interferes with them, or to mar the gracefulness of columnar composition—in which so very much depends upon that sort of proportion, which is, as often as not, wholly disregarded by those who affect to be most scrupulous as to proportions of detail. The architect of the Alliance Office, for one, has certainly not attended to the proportion alluded to, for he has put his columns so far apart, that they serve chiefly to produce a straggling effect; and yet, owing to the windows between them, the whole has a very disagreeable, crowded, and squeezed up appearance. The centre intercolumn, containing two treble windows, one over the other—an arrangement which it is hardly possible by any means to render tolerable, is so wide, as to amount almost to a gap in the composition. Of course this was occasioned by the gateway below, which is in itself so wide, that it also forms a gap, and seems to require columns to support its lintel or architrave; therefore, unless intended for carriages to pass through—which does not appear to be the case, had the opening been a little contracted by two columns being placed so as just to clear the piers, the effect would so far have been better, and the passage through the building would have been just as wide as at present.

II. Professor Hosking is not the only one who has expressed a very contemptuous opinion of Vitruvius; for a writer in the "Annales des Batimens" has spoken of that "venerable authority" in terms that must make his admirers absolutely shudder. He does not scruple to apply to the "Father of

Architecture" and its legislator, the character of "Le plus credule et le plus ignorant des compilateurs"! consequently, if such be his opinion of the idol, we may take it for granted that he entertains no great respect for the intelligence shown by the worshippers of it—by Vitruvius' translators and commentators, or any of those who look to his writings as oracles. It may, however, be suspected that a very great many who have the name of Vitruvius always in their mouths, know very little of his writings, and would be strangely perplexed if asked to explain what they had learned from them, or in what way the study of them has conducted to more enlightened views of the art. Far easier would it be to show how such study has cramped architecture, and has tended to render it a plodding pedantical system, governed not by principles and artistical feeling, but by merely conventional rules—by rules which, if implicitly followed, without regard to the circumstances of the particular case, may operate most injuriously.

III. In architectural history, it is almost invariably the practice to make a full stop at the very point where preceding writers have left the subject, and from which it is most of all desirable that it should be taken up afresh, and carried onwards. From the commencement of the 18th century, everything in the shape of a connected history of the art ceases. What information relative to it is to be obtained at all, is scattered about in fragments through numerous publications, either literary or graphic; nor has any one yet thought it worth while to collect and arrange, to add to and extend such materials, and work them up into consistency and shape. Almost might it be supposed that the art was now altogether extinct, and that since the period above-mentioned, scarcely anything above the feeblest mediocrity has been produced; things

"Too vile to praise, too decent to be damned;"

albeit some of them have been puffed off in their day as first-rate, classical, and everything else that is excellent.

Even a mere matter-of-fact chronicle would be serviceable in its way though immeasurably short of a critical history, which, by fearlessly pointing out the errors of the past, might lead to improvement for the future. So long as there was no Royal Institute, there was little hope of architecture receiving that attention to which—whether justly so or not—it is supposed to be entitled as an artistic, intellectual, and æsthetic pursuit; and since the Institute has been established, there is not one ray of hope more; therefore, even less hope than ever of such proving the case. Sorry I am to say that the Institute seems to be quite satisfied with having got the pap of Royal patronage—which I suspect to be worth about as much as Don Armado's remuneration.

IV. Putting aside elementary or technical works, there has of late been a strange dearth of architectural publications in this country, which, to whatever else it may be owing, can hardly be attributed to the paucity of buildings erected within the present century—many of them of a kind too, which, let them be what they may, are of considerable pretension, and ought, therefore to be well-worth studying for their design and the taste exhibited in them. Undoubtedly no immediate, nor very tangible advantage would be derived from the publication of their works to the actual authors of them. Those who have shown the greatest ability, have, least of all, occasion to advertise themselves and their productions; and as an affair of pounds, shillings, and pence, they show their prudence by not doing what they might in the end be out of pocket by. But then, on the other hand, those who have done the most and the best, can generally very well afford so to tax themselves—if only for the sake of showing that they have aimed at something more than professional emolument; and that while they look back on their productions with the feelings of artists, they also look forward to extended fame from them, and that not merely at home, but wherever the art is cultivated. Would the names of Schinkel and Klenze have been already so well known in this country—and, indeed, throughout all Europe, had not their designs been published? Hardly; at least, had they not been so given to the world, comparatively few would be able to judge what they really are, or to profit by the studies they afford, and the ideas they haply may suggest to other minds. This last circumstance, by-the-by, is one of greater importance than is generally conceived: collections of architectural designs seemed to be looked upon by most persons—not excluding professional ones, as little better than books of patterns, of no other use than as something may be copied out of them at once. Hence, not only the open plagiarism which in any other would be stigmatised as disrespectful, but frequently the vilest botching also. Wide, indeed, is the difference between taking something out of another man's design, and seizing hold of an idea suggested by what may there be shown, which idea, so far from being bor-

rowed may be altogether so different from anything shown in what gave rise to it, as to render it impossible for any one to trace it to its *punctum saliens*.

MARTIN'S CEMENT.

In our last number we slightly alluded to the above cement; since then we have been able to obtain some additional particulars, which we now lay before our readers.

The common qualities of the cement are noticed in the circular in general terms, and the method of working it for common purposes explicitly laid down. It is, therefore, only necessary for us to point out here its various applications.

First, then, *Floors*. These are formed with the cement laid on a bed of concrete or arching. The cement is mixed with fine river sand, or with tile dust or puzzolana, as may be most liked, and laid on the concrete about $\frac{3}{4}$ inch thick. If Portland or Bath stone is wished to be imitated, the grit is mixed with the cement. After being properly trowelled, it is jointed to imitate stone. If, however, an ornamental floor is wished, a ground work of cement and sand is laid upon the concrete about $\frac{3}{4}$ inch thick; colours are then mixed (dry) with the cement, and the floor may be laid either to represent octagonal tiles or alternate squares as may be desired in any colour and any pattern. If an inlaid border should be preferred, the pattern is cast in slabs, and the colours let in the spaces left according to the design. Some elaborate mosaic in imitation of tiles found in one of the courts of the Alhambra, the colors of which are blue, white, and burnt sienna, and the size about eight inches wide, can be executed (as they have been already) at about 2s. 3d. per foot run. Of course, a more simple pattern with less variety of colour would cost less.

Stairs. The steps are formed in York stone, rough, and covered with the cement to imitate Bath, Portland, or any other stone; or simply by itself, as executed by Mr. T. Cubitt with great success.

Walls generally are worked in the manner described in the directions for use in the circular. At the New Sun Fire Office, and generally, the panels are worked in the cement mixed with sand, and the mouldings run in the pure cement. It is, of course, easy to imitate any stone or colour. At the Swindon station of the Great Western Railway, it is intended to finish the walls of the engine house of a light buff colour, rubbed down and stopped, and finish it with slight polish; the cost of this would be about 4s. 6d. per yard super.

Architraves, surbases, skirting, and every description of moulding can be worked in it. It presents a finer face and cleaner aris than wood; requires less paint; neither shrinks nor cracks; is not so liable to injury; and while in the most simple descriptions of work it is cheaper, in the more elaborate its economy renders it far superior to that material. Chimney-pieces, columns, pilasters, and every description of work can be executed in this cement with polish and splendour of appearance equal to scagliola in imitation of any marble; and while the cost of scagliola varies from 5s. to 8s. 6d. per foot, super., this cement does not exceed 4s. 6d. It is equally as easy to remove as marble, and is as readily repaired when injured. Great beauty might be derived from a judicious employment of mosaic with the imitation marble. The Grecian fret in white or blue (Prussian), let in imitation sienna or *giallo antico* in the jambs of chimney pieces, the archivolt of doors, friezes, panels, &c., can easily be conceived. The cost of such work, if the pattern were not very elaborate, involving a great variety of colours, would not be so great as if executed in finished scagliola without mosaic—merely the simple marble. In cases where polychrome decoration is sought, as in some Gothic cathedrals and the varieties of the Lombard style, the advantages of this cement is apparent; being as hard as marble, and the colours equally as durable. Gothic pillars can be worked round a core of brick work, and an endless variety of ornament which is characteristic of the style either cast or moulded in this cement may be executed at a cost trifling in comparison with either wood or stone.

REMARKS ON THE LETTER BY "AN ADMIRER OF ARCHITECTURE."

SIR—Notwithstanding that you yourself have already replied to "An Admirer of Architecture," in the pertinent and forcible editorial note attached to his letter, I could wish, as the writer of one of the articles he has commented upon, to be allowed to say something further, since he appears to have greatly misconceived one or two points. Misconceive he certainly does, when he supposes that the remarks on the "Threadneedle Street structure" were penned chiefly for the purpose of crying up that building, and decrying almost every other production of architecture in the metropolis at all similar in style, or sufficiently so to admit of any comparison. I certainly did bring forward many instances of buildings—some of them tolerably recent ones—and however unfair or illiberal my estimate of them may be, "Admirer" seems to acquiesce in it, for he has not attempted to gainsay it, by pointing out merits in them, or any one of them, to which I had wilfully shut my eyes. That he objects to my having expressly named several buildings which I hold to be exceedingly tasteless and mediocre, I can hardly for a moment suppose; or if he does so he is most strangely inconsistent, because he himself says it is fairer to allude to particular parties, or to their respective works, than to deal in vague and sweeping denunciations which criminate all alike, without distinction. If, therefore, I erred at all, it was not in naming any, but in not naming every one of the buildings to which I could easily have adverted, as striking examples of false taste and the "pseudo-classical" system.

I am wrong, however, in saying that I could have done so "easily" for it would have been a tedious task to point out, one by one, all the instances of the kind that might be enumerated. Still, from those which I did specify, it will not be very difficult to guess what others I should include among them; nor is there much danger of any one's fancying that I should exclude from my list the British Fire Office in the Strand, or the church in Wyndham Place, both of them the productions of men who rank high in their profession—men who, it is to be presumed, are not of "uncultured minds," for they have travelled, and, it may be presumed, have studied also, and applied themselves to their art with more than ordinary diligence. Advantages they certainly have had that do not fall to the lot of every one in the profession, for they have had opportunities both ample and frequent put in their way,—one of them especially; yet how far they have turned them to account, or what particular talent or taste they have manifested, may be judged from the above-mentioned specimens of it: not from them alone, but their works generally.

Under-rate their buildings, and many others which enjoy no small degree of credit with the public, I most certainly do, because I rate them at a very much lower value than they have hitherto passed at, and of course, as I myself conceive, at a much juster one, and more corresponding to their actual worth as productions of architecture. Sooner or later, things which have been greatly over-rated sink to their proper level; although the first attempt to correct public opinion in regard to them may appear invidious, if not malevolent, especially in those cases where an imposing reputation has been acquired, that carries with it a degree of authority which persons in general are unable to dispute, and which those who are able do not care to oppose. In matters of literature and art, and not least of all in architecture, the influence of names is exceedingly great, to a degree that is not only magical, but positively injurious, for it causes that which requires to be assayed to be set up as a standard of excellence—an authority to which all ought to bow down. A reputation may stand very high upon the whole, and not undeservedly so, and yet be no pledge whatever for excellence in many productions that may be sheltered by it, as being productions of the same mind. Such I conceive to be the case with regard to Sir Christopher Wren: as the author of St. Paul's, he is fully entitled to all the honour that has been heaped upon his name, but all his other works are so immeasurably inferior—some of them, indeed, so utterly unworthy of being considered productions of intellect or art—that it is with difficulty we can persuade ourselves that they were conceptions of the same mind. The fact, indeed, of their being by him admits not of doubt or dispute; but internal evidence afforded by the things themselves is wanting altogether. Nevertheless, because such is the fact, and for no other reason, our admiration is claimed for everything that passes under his name, without reference to intrinsic merit, or without the least suspicion that what is by the author of one of the noblest monuments of English architecture can be other than truly excellent in itself. Thus is a name converted into a positive standard of merit; criticism is merged in mere prejudice or else hypocrisy; admiration is affected where it is not felt; the expression of opinion is reprobated as flying in the

face of unquestionable authority; and uninquiring deference to and superstitious veneration of great names are inculcated, which operate in reality injuriously to the real interests of art, and impede its advancement. We bow down to names, and make them our idols. It is expected that those of Vitruvius, Michael Angelo, and Palladio, should be worshipped by us: to doubt, to call in question, or even to inquire into the real merits of those who have been so pinnacled aloft, is regarded as a species of actual profaneness;—which may, after all, be very right and prudent, for some reputations of the kind are by no means of a description that will bear being handled and closely inspected; and most unpleasant must it be to their admirers to have unsightly flaws and defects pointed out in their idols, and to hear objections started which they know not how to refute or ward off.

But I am now wandering very wide astray, and must therefore skip back at once to "Admirer" and his remarks. Among them is one from which it might be inferred that I had deprecated, or attempted to dissuade from, the study of Stuart's "Athens," and other works of that class. Now what I complain of is precisely the reverse; that they are learnt by rote, and copied without being studied scarcely at all; for were they studied, their spirit would be caught, and infused into modern works, which would nevertheless be marked by original feeling, some novelty of treatment, and some freshness of ideas. Instead of this being done, the works alluded to are made use of as little more than mere books of patterns; and wherever they are deviated from at all, it is more frequently than not entirely for the worse, it being done not with any attempt to advance a step farther than the originals, but rather to retrograde a step or two back. Thus while we have Grecian-Doric porticos professedly after that of the Parthenon, or the Theseion, the resemblance extends to no more than the columns themselves; for although they may be copied with facsimile accuracy, as if fidelity in that respect was in itself all-sufficient, so very greatly are the original buildings departed from in almost every other circumstance, that almost all in them that amounts to design, or contributes to effect, is entirely obliterated. Inner columns and depth of pronaoes behind them are omitted, and metopes and pediments are left blank, as if those were altogether matters of perfect indifference and no moment, although to vary ever so little from exactness in the minutest details in the columns and mouldings of the entablature would be deemed a great license. Now were Grecian architecture really studied in a liberal and artist-like spirit, such would not be the case. Its orders and other features would be looked to as standard types of the style, as models upon which our taste in that style is to be formed; not—as is now the case—as stereotype copies which admit of no modification nor any diversity of expression, be they applied ever so differently from what they are in the structures from which they are derived. Of course the junior student must begin by copying from Stuart, in order to familiarize himself with those models perfectly, and as preparatory to farther study of their character. But the misfortune is that very few indeed ever think of getting beyond that first step; with copying they begin, and with copying they end. But the ancient orders, we are told, will not bear being trifled or tampered with. Yet, surely, to make use of them with artist-like intelligence and freedom, and to treat them with congenial taste, is quite a different thing from tampering with them; and that it is more than every one is able to do, may be taken for granted, because it is not every architect who is an artist; but to maintain that it is more than any one is able to do, would almost be equivalent to saying that no architect is an artist, or can be trusted for a moment if he attempts to innovate in matters where others are content implicitly to follow those who have preceded them. So much for the difference between studying Stuart, and merely tearing a leaf out of his book, as may serve immediate occasion.

But, it is said, "Mr. Barry has his book of reference, too"; no doubt, otherwise he would hardly have made himself so familiar with the genius and capabilities of the style in which he has shown mastery; but then he has evidently turned it to a very different account than those do their "Stuart," who do little more than merely take from it the exterior or façade of a portico, to stick up where it shows itself to be merely borrowed, and perhaps most tastelessly misapplied. Many details and some entire features in some of Mr. Barry's most successful Italian designs may certainly be traced to previous examples that have been delineated; yet that hardly amounts to copying, for they are frequently so very greatly improved upon, and recombined with so much taste as to acquire a heightened charm. Of many the merit hardly shows itself in the original compositions, where there is generally together with much to please, almost always something to offend more or less, whereas our English architect's productions are stamped by a refined elegance diffused over the whole, and kept throughout. But if, as would seem intended to be insinuated, any else might, by pursuing the same method, accomplish with

facility quite as much as Mr. Barry, why then, in the name of common sense, do they not do so at once, and deliver us from such specimens of Italian, as the City Club-house? And why do they not adopt the same with regard to Grecian architecture, and deliver us from the mawkish and spiritless schoolboy copies of it that are now served up to us *ad nauseam*? The reason why what is apparently so easy is not done, is perhaps that the taste requisite for accomplishing it is wanting. And I fully agree with "Admirer," when he ascribes so much to that natural taste which can neither be learnt nor unlearned; cordially, also, do I assent to his opinion, that quite as much depends upon the spirit and taste with which a style is treated, as upon the style itself.—But it is time to conclude this long letter, and I will, therefore, merely add that I wish "Admirer" had distinctly specified the particular parties or their works, to whom he alludes with so much approbation as "examples of design in distant parts of England." And as this letter will, no doubt, meet his eye, I hope it will induce him to do so now, for most happy shall I be to learn that there are productions of very great merit, which are as yet hardly known even by reputation in this part of the kingdom.

I remain, &c.,
THE AUTHOR OF THE ARTICLE ON THE
THREADNEEDLE STREET STRUCTURE.

REVIEWS.

Architectural Illustrations of Windsor Castle. By MICHAEL GANDY and BENJAMIN BAUD, Architects. *With a Concise Historical and Architectural Account,* by JOHN BRITTON, F.S.A., author of "*Architectural and Cathedral Antiquities*," "*Dictionary of Architecture*," &c. Folio, 40 plates. London, 1842.

Now that it is completed, or rather brought to a conclusion—a very great deal that would have been the most interesting of all as graphic illustration, and perfectly new to the public, being left altogether untouched—and now that we have the letter-press before us, we can speak of this second work on Windsor Castle more decidedly than when our notice was confined to some of the plates during its progress. Whatever be its deficiencies in other respects in regard to illustrations, it gives us one which was neither promised, nor is even now mentioned in the list of engravings, one for which we were so totally unprepared that it made us stare; and no doubt our readers will stare too when told that it is no other than an illustration of—"Benjamin Baud, architect"—and as it would seem, the architect of Windsor Castle, a large view of the building being introduced at his elbow. This is certainly original—perhaps *un peu fort*, and what most people may consider a piece of puppyism; at any rate it is calculated to call forth comments and remarks, not very likely to be altogether agreeable to the gentleman who has hit upon a notable method of advertising himself. If there was to be the portrait of any one at all, it should most assuredly have been that of SIR JEFFRY WYATVILLE—of the individual who remodelled the Castle, and gave it its present form and character—of the architectural composer and performer, not of his "bellows-blower"! Or is there something more in the matter than meets the eye—is it pregnant with a meaning that might not be expressed otherwise than thus hieroglyphically? Can it be intended as a delicate insinuation to the effect that the designs for the alteration of the Castle, hitherto attributed solely to Sir Jeffry, emanated from Mr. Baud, and that it was he who furnished his employer with ideas for his grand work? It is possible, because such things have happened ere now; for, as his friend Mr. Britton can tell him, works have been given to the public under the names of parties who were only their ostensible authors, the real authors being kept out of sight, behind the scenes along with other lumber. In the literary world, it is no very uncommon practice for those who have a name worth borrowing, to lend it—or rather to sell it to publications they never wrote—probably never read. There are tricks in all trades; why not then in architecture as well as in authorship? why may not "the truly estimable Sir Jeffry Wyattville," as Mr. Britton here calls him, have, if not sold his name to, have purchased of Mr. Baud, services very far more important than those usually expected from an architect's assistant? Strange and ugly suspicions come across us; and so far from being removed, they are rather confirmed by another circumstance in this very remarkable portrait, which, though not exactly an architectural illustration, may be intended to throw some light upon a matter in regard to which the public has hitherto been kept entirely in the dark. What we allude to is the plan of the "West of London and Westminster Cemetery," which is also introduced as one of the accessories or "by-play" touches in the portrait. Now that is avowedly the production of Mr. Baud—one

which few in the profession will envy him the credit of, however they may envy him the job—therefore the juxtaposition of the two subjects, the Cemetery and the Castle, expresses as clearly as can be done in painting, that both are productions of the same genius.

If such be not the meaning, what meaning at all can there be? Is it merely a piece of waggish mystification on the part of Benjamin and his painter? or shall we say that the thrusting in his portrait at all into the work has no other signification than as a sign of Benjamin's conceit? Be that as it may, we have no particular cause to object to its appearance, since it has served in lieu of other proem; and although it has detained us rather long, it is quite as pertinent, quite as much to the point, as introductions to articles of criticism generally are; not very much more rigmarole, not altogether so hackneyed, and probably a degree or two less dull. Possibly, too, what we have said may lead some one to take up his pen, and favour us with a volume, or at least an essay, of "Historic Doubts" as to whether Windsor Castle was the work of Jeffry Wyattville or Benjamin Baud.

We now turn at once to the architectural illustrations themselves, which are certainly very satisfactory as far as they go, and of a more popular character than those in Mr. Ashton's work, because a great many of them are pictorial and perspective views, consequently possess greater interest for persons in general than geometrical drawings, to which the other work is confined, and which, to those who perfectly understand them and properly value them, are in themselves most indispensable and important of all, but do not always convey sufficient idea of the effect of a building so represented; more especially when, like Windsor Castle, it happens to be a complex and extensive pile, composed of parts and masses receding from or advancing before each other, in a manner intelligible enough from the ground plan, but nevertheless requiring to be distinctly expressed to the eye, perspective. While the want of delineations of the last-mentioned kind as accompaniments to the strictly architectural drawings has rendered many publications wholly unattractive except for those who make use of them as studies; many graphic works—of first-rate merit as such—are by no means so valuable as they would be, were some geometrical explanations of the subjects they contain, introduced into them. In this respect these illustrations of Windsor Castle are got up in a judicious manner, for not only is there a series of elevations showing the whole of the exterior, but also several plates of details and parts at large. But then, there is one most unaccountable omission, which detracts very materially indeed from the serviceableness of the work, there being not a single ground plan, not even of the principal floor, consequently the book is strangely incomplete, since no information whatever is now to be obtained from it relative to the internal arrangement of the building, the accommodations provided in it, the disposition, form, or size of the various apartments, their respective names and purposes, and the manner in which they are either connected and made to communicate with, or cut off from each other—particulars highly important to be understood, and which, in this case, would hardly be passed over with indifference even by those who would bestow scarcely any attention upon plans in general.

If the omission was entirely owing to oversight, it was very strange; if on the contrary, an intentional one stranger still, and utterly inexplicable; nor is such omission rendered at all less glaring by the thrusting into the work such a very superfluous "illustration" as is the portrait—of one, too, who is not the most illustrious in his profession. Gladly would we, and most others also, we suspect, give that, and not that alone, but one or two of the other subjects in exchange for a plan of the castle, more especially as there are one or two subjects of comparatively very little value. There, is, it is true, what is well enough in its way, and very acceptable in itself, namely an outline block, or situation's plan of the castle and the buildings immediately connected with it, yet that shows only the external arrangement, and what might be tolerably well comprehended from the views. If therefore we wish to ascertain how the interior of the castle is laid out, and what alterations and improvements Sir Jeffry introduced into it, so as to render it more habitable than it was before, we must have recourse to Mr. Ashton's work, which gives not only detailed plans of the whole of it in its present state, but others showing what it was previously to the late alterations and additions. It is evident from them that the architect had neither few nor small difficulties to contend with, and it was, perhaps, rather fortunate than otherwise, upon the whole that such was the case, since had it not been for them, he would probably have missed some of the very best points in the plan, to which he was driven in order to get over those obstacles. There certainly are not only some novel, but some striking and happily-contrived parts within the Castle; nor is it in the least degree unreasonable, therefore, if we make it a complaint against both the publications which are devoted to the subject, and against the present one more particularly, that they have done nothing to gratify our curiosity

relative to its internal architecture. To say that such "illustration" formed no part of their plan, is anything but a satisfactory excuse for the omission, the very thing complained of, being, that what was very essential to its completeness has been purposely excluded from it, and that no care has been taken to guard against disappointment by making their titles announce that both works confined architectural illustration to the mere exterior of the edifice. Not very much more satisfactory is to be told, as we are by one of them, that if further illustration has not been attempted, it is because Sir Jeffry himself considered the interior to be comparatively—a failure, shall we call it, or merely say, comparatively unworthy of attention? and acknowledged, virtually at least, if not expressly, that instead of being left to his own judgment, he had been controlled by, and compelled to give way to, the false taste and the caprices of his royal patron, so far, therefore, in a manner disowning it as his own work, or a work at all worthy of him. It is alleged, in excuse for not showing the interior, that many parts of it, and much of its present decoration, are likely to be altered and fitted up afresh, some time or other. No doubt, for what structure of the kind escapes retouches from time to time; but it is not at all likely that alterations to any extent will take place within the castle for a very long while to come; nor whenever made, would such alterations in any way diminish the interest and value of illustrations which in such case would become faithful records of what the interior of Windsor Castle is in its present state. Whatever, too, may be the case with respect to the strictly private apartments, or to those intended for the accommodation of visitors, there must, at any rate, be some if not several which are more or less worth being architecturally explained, or graphically described, on account of their importance, their character, and their effect. Or are we to conclude after all, that as far as architecture is concerned, there is absolutely nothing within the castle that merits attention, nothing in any degree worth studying, nothing to repay curiosity? Are we now to suppose that the "Grand corridor" itself, which has been spoken of as something quite extraordinary and superlative, is in reality "no better than it should be"—of but very *so-soish* character—perhaps somewhat too Strawberry-Hill gothic in style? And then the Waterloo chamber, St. George's hall, the state entrance and staircase,—are not they worth showing either in views, or by particular sections of them? It is true these last-mentioned parts of the interior can be seen by the public; but if that be any good reason for no illustrations of either kind, being given of them, the same reason might be made use of as an argument to prove that there was no occasion for either of the publications, which are now entirely devoted to the exterior of the castle, since the latter is, by far, more open to public inspection, and that freely, which is certainly not the case as regards any part of the interior, where no time is allowed for examining, much less for studying or deliberately taking note of what we are permitted merely to view, and of which, therefore, only the general effect can be judged. In order properly to understand the anatomy, if we may so term it, of Windsor Castle, full as many plans and sections (both general ones, and particular ones on a larger scale,) besides views, would be required, as there now are engravings of the exterior both in the work before us, and its predecessor. Though this is no exaggeration, as any one who understands the subject may convince himself, by examining the plan in Mr. Ashton's work, it would, we admit, be unreasonable to look for illustration to anything like that extent, except, perhaps, in a work published by government—and for that being ever done in this country, we might as well look for a miracle, or look for Windsor Castle's being swallowed up by an earthquake.

Because it could not be done after that extravagant fashion—as, no doubt, what we have above hinted at will be considered—is no reason, however, why nothing of the kind should have been attempted. Thankful should we have been for something, had it amounted to no more than three or four judiciously chosen sections, through some of the principal and most interesting parts of the interior; for the sake of which we would willingly give up double that number of the present illustrations, since some of the latter are hardly required at all, there being little in them besides what is shown in other portions of the general elevation to which they belong. With the exception of a single section, and that not through the upper floors of the building, no part of the interior was shown in that one of the two works which was first completed, it was therefore to be expected that Messrs. G. & B. would have taken advantage of that circumstance by introducing into their own publication what would have formed a new and highly interesting feature in it. Instead, however, of doing more in that respect, they have, as we have already observed, done less, for their work contains not even a plan, so that the interior of the castle is left totally unexplained by it. However well, therefore, they may have manoeuvred in other respects, they have certainly shown no very

great tact in thus flinging away the very best trump-card of all that was in their hand. The only person who has turned the rival publication to his own advantage is their editor, and after what fashion he has done so, we shall presently say.

Admitting that it would have been too expensive to employ the pencil for describing the interior of the castle or any part of it, what was not attempted to be done by the pencil, might have been accomplished by the pen—at least, as far as accurate and intelligent description can supply the place of drawings, without the aid of which last, the best written description cannot be thoroughly satisfactory as explanation, however interesting it may be in itself, and however instructive it may have been rendered, by the criticism mingled with it. For such description, however, a very different pen is required from that wielded.

Mr. Britton, in the preface, boasts of his long acquaintance with Windsor Castle, and of having repeatedly written and pronounced various historical, descriptive, and critical remarks on it. If so, he must quite have exhausted his powers of description and criticism before he wrote the present account of it, for it contains nothing that amounts to either the one or the other.

Ancient and Modern Architecture. Edited by M. JULES GAILLHABAUD. London, Dido

We have received from the enterprising firm of Didot and Co. of London and Paris, the first, or specimen number of a serial work intended to illustrate the several styles of architecture and their application to various classes of buildings. Commencing with the Celtic and Pelasgic, the rude heaps of barbarous ages, the architecture of the east and the west, of the Pharaohs of the present day, is to be exhibited from authentic examples. Thus the present number contains three engravings of the Speos, dedicated to Athor at Ebsamboul in Nubia, and two of the Kailasa at Ellora, accompanied with descriptive letter-press from the pen of M. Jules Gaillhabaud, an eminent archaeological writer, and translated and extended by Mr. F. Arundale. It is evident that the field is wide, and the mode in which it is to be entered is sketched in the prospectus. Thus we find the temple of Edfo in Egypt, that of Theseus at Athens, the temple of Segesta, the Basilica of Constantine, St. Clement at Rome, and Torcello near Venice, the Church of St. Vital at Ravenna, the Mosque of Ehn Touloun at Cairo, the Certosa of Pavia, and the Cathedrals of Bonn, Fribourg and Paris, from part of the intended course.

The first and most essential recommendation of the present plan is, that it is cheap, the number before us containing four plates costing no more than four shillings; then we may remark that the engravings are admirably executed, and that no expense has been spared in rendering them worthy of a work of such importance; the letter-press is also exceedingly good. The list of proposed contributors includes Messrs. Gomard, Champollion, Figeac, Langlois, Albert Lenoir, and Radil Rochette; while the English translation and illustration is undertaken by Mr. Arundale. All these advantages are sufficient to recommend it to the public patronage.

ON DRAINAGE.

Lecture by Mr. Smith of Deanston, delivered before the Members of the Royal Agricultural Society, at Bristol; Wednesday, July 13, 1842.

(From the Bristol Mercury.)

I need not, before such an audience, say that to the agriculturist the dryness of land is of great importance—that, in fact the dry condition of the soil is the foundation of all good husbandry. It is beneficial, in the first place, to the working of the soil; it is beneficial also, to the after-growth of the plants, and there is scarcely any labour connected with agriculture which is not facilitated by the dryness of the soil. If we look on the face of nature we may gather instruction on this subject; for if we find a tree stronger than its neighbour, we shall find that there the soil is deep and in a dry condition. If we see a stronger and darker coloured herbage growing on the hill side, there the soil will again be found deep, and in a dry condition. There is not one of the various soils on the surface of the United Kingdom which will not be much improved by being placed in a dry condition, if they are not so by nature. I would say that even on a subsoil of gravel or sand the introduction of the thorough-drain system would be highly beneficial; but as there is only a small portion of that sort of soil in this country, the greater part being superimposed upon a wet soil, it becomes of the very first importance to the progress of improvement in agriculture that means be taken to render the condition of the soil dry. Many attempts have been made with that view, but they have generally failed, in consequence of not having been done on a proper principle. The first system introduced into this country, was to excavate deep drains, for the purpose of catching the water that rose from below in the form of spring water. These were, to a certain extent, effectual, and no doubt removed a great deal of the difficulty which agriculturists had to contend with, on land partially wet and partially dry; but until the introduction of the thorough drain system, there was not

he power of draining land, on whatever sub-soil, resting, and rendering it thoroughly and completely dry. The purpose of this lecture is to illustrate, first, the principle on which this system acts; then, to show the advantages which would arise to the agriculturist in carrying on the different processes with respect to the various crops; and then to explain the modes employed to render this drainage effective, both as to the cutting of them, and to the preservation of the openings made for the escape of the water.

[Mr. Smith here illustrated by a diagram, his method of thorough draining; the soil, the subsoil, the drains, &c. being represented.]

In referring to two lines, representing the directions of drains, he stated that he had drawn one at a greater inclination than the other, to show the advantage of making the drains deeper than they generally were. The prevailing practice was to make the drains two feet deep, but he preferred an additional six inches—for this reason—that it was of great importance to allow the water to go off as quickly as possible, and this advantage was secured by cutting the drain to a greater declination. People were apt to suppose that at a great depth water would not go off at all, but this was a mistake. Another advantage arising from a deep drain was that it allowed the whole bank of soil to become completely dry, and it consequently required a very heavy rain to wet it. The action of the atmosphere, too, required to be taken into account. He would not enter upon the chemical question, but it was well known that soils were much improved by the action of the air, and this advantage could only be secured after the water was withdrawn.

To render the field completely dry, it was necessary that a great number of drains should be cut, and that they should be laid off in parallel lines beginning at the highest side of the field. This secures a thorough drying, and it has been found that when the lines run parallel, much greater effect is produced than when they are drawn across. When drawn across, the drains may catch the water, but experience has shown that it does not run off so readily.

With regard to the distance at which the drains should be placed, that will depend on the nature of the soil. If the field has been subsoiled, it is of less importance; because the plough will form artificial channels in the soil below. If it is a stiff soil, it will keep long upon the surface; and the more free the soil is, the greater tendency it has to allow the water to pass; so that you will find that, on a stiff soil, such as the stiffer clays, taking into account the nature of the subsoil and the soil itself, about the same drain will serve on all soils. The distances in use are generally from 15 to 20 feet; in some soils individuals have been induced to put in the drains at 12 feet; but I conceive that that is, in some degree, throwing away money. From observations which I have made myself on all sorts of soil, in different parts of the country, I am inclined to recommend about 16 to 20 feet as the distance from one drain to the other.

The way in which I usually proceed in draining, is, first to find a good bottom-level to run the drain into. And here I may remark, that in some parts of the country there is sometimes difficulty in getting an open level to carry off the whole water of the district; but I think that by a proper application of the principles of engineering, it may be accomplished in most situations; because it is found that if proper channels are executed, a larger quantity of water will be discharged with a very small fall. In an instance in which I was engaged in the endeavour to carry off water, I found that in a drop of four inches in a mile, thirty feet wide and six feet deep, I could discharge 300 tons of water per minute; which is much more than would fall in a very extensive district indeed. So that I have no doubt, it means be taken to carry off the main level, that a fall may be had.

With regard to the fall of the great main, the receiving drain, I should make that drain if possible about four feet deep—three feet six inches will do; but in order to have a drop from the one drain into the other, I usually make the main drain four feet deep, the receiving drain three feet deep, and the parallel drains two feet six inches. When there is any rise in the ground, or any hollows over which the water can very well flow, it is necessary to make a cad's drain. That should be made about six inches deeper than the other drains which fall into it; then running on, it discharges itself into the main drain.

With regard to the manner of executing the drains, there are various modes recommended, and I have found, on looking to land which has been drained a great many years, that when the draining has been performed carefully, all the different modes employed for the purpose of keeping the drains open have been quite effective. Indeed, a great deal of the want of effect in the duration of drains has been owing to the bad execution. In some instances faggots have been introduced for the purpose of preserving the openings of the drain, and these have been found to continue and to preserve the openings in a perfect state for nine years—in some instances I have ascertained for twenty years.

In Scotland the peat-top is frequently used to form the tiles for drains. It does pretty well in clays which are pretty stiff, but does not do so well in softer soils; in the same way, in some of the sandy soils, the sides not being

sufficient to resist the pressure of the top, the tile gradually sinks down and closes up the drain.

Another mode of filling drains is by stones broken into the usual size for making roads; and, although much has been said against the use of this sort of filling, I have found from experience that when properly executed the work is as durable as can be required. In most instances where stones can be had, and where tiles are expensive, I should very much prefer them to the tiles; and there is this advantage connected with it, that it prevents any vermin from travelling in the openings of the drain, such as rats and mice, which do a great deal of mischief. The great point is, to be very careful in covering over at the top. As soon as wet comes, the sand and other materials silt down into the stones, and they are completely choked up. I have found that drains not carefully executed, were completely destroyed in the course of a couple of years. On the contrary, if drains are so packed that the water falls down on both sides, (the parts over-lapping each other) there is no opening whatever for the sand to find its way down. If drains are carefully cleared in this manner, I will warrant their duration for almost any period of time. I have executed myself about 130 miles of drains in this way, and have had them all filled with stones; many of them have been done 15 years, and there has not been a single instance of failure.

Many persons who have visited my farm have asked whether or not the drains would be choked up in particular positions. I have always asked them what positions they referred to, and have opened it that they may see; and in no instance have I found a single drain choked up. I have the drains of 100 acres all discharged into one pond, provided for the purpose of seeing how much deposit came from the drain; and although we have had heavy rain, I have never seen the water in the pond tinged as if there was much soil in it. I can, therefore, safely recommend stones as a very sufficient drainage; and in many parts of the country it is much cheaper than tiles.

The next filling which has been used for preserving the openings of drains is the drain tile. These are usually made of clay, and burnt. They are found to be very handy and very useful; and where stones are not to be had they are to be preferred. But there are districts where the clay tile cannot be procured at any reasonable price; they are usually 30s. a thousand, but in some districts they are not to be had at all. Lord James Hay has recently discovered a method of making them of concrete stones cemented by lime; and so far as I have made any calculation of the expence, I think that in most instances they will come considerably cheaper than the brick tile, and, if executed on the ground, where they will not have to be carried far, the breakage will be found to be very little, and they will be found to be exceedingly durable. We know that the cement made of lime is more lasting when covered up than if exposed to the atmosphere; instances of this may be found in the lime frequently discovered in old buildings, which has been found to be perfect after hundreds of years.

There are two other modes of making drains—peat earth has been cut into a shape somewhat like a hollow wedge; and a sort of instrument has been made for the purpose of cutting peat earth into the form of the tile, so as to produce an opening not liable to the objection of the wedge, which frequently sinks and fills up the opening. A stone is frequently used to lay the concrete tile upon, and prevent its sinking. It is also made of concrete.

Much has been said with regard to the application of this system to different soils; and many persons have expressed the opinion that, in some of the very stiff clays, drains of this sort would not be efficacious, and that the application of the subsoil plough after the draining would have no good effect. With the view of showing the beneficial results, both of draining and subsoiling, I have brought some specimens of different clays, in order to show what improvement can be made. Here is a piece from the Pass of Stirling. This kind of soil has been cultivated from a subsoil, and has been known to produce excellent crops of Swedish turnips. Here is another very hard clay from Yorkshire.

A gentleman inquired how long after the subsoiling the land assumed a different character.

Mr. SMITH—Almost immediately—in the very first year. It requires some years before it becomes adapted for a turnip soil. I have a specimen of some soil which twenty years ago was so extremely stiff from the alluvial deposit in the Pass of Stirling, that it required to be broken with large mallets, to reduce, mechanically, the great lumps of soil. Thorough draining or subsoiling was never thought of till about twenty years ago, when this land was first drained; and now they get from it very splendid crops of turnips, and in almost any season. Here is a piece of the improved subsoil before having been drained by the subsoiling, the same as the other. While we are on this point, I will produce the two specimens of subsoil from my own farm.

A gentleman wished to be informed of the nature of the soil in Mr. Smith's farm.

Mr. SMITH—It varies. In some parts it is sandy clay, and in others, clay perfectly impervious to water. When I first began to subsoil there was not more than three or four inches of active soil, properly so called, for growing plants; after a labour of about fifteen years I have now an active soil of sixteen inches, and can turn over that in any part of the farm.

A Gentleman.—How near are the drains in order to produce that result?

Mr. SMITH.—Twenty feet. Having thus described the various modes in which the drains have been formed, and having stated that, so far as my experience and observation go, I think a distance of about eighteen or twenty feet from drain to drain is a proper distance for almost any subsoil, I shall now proceed to detail the application of the subsoil plough.

When I first began to cultivate my own farm, although I had put in the drains, I found they were not so efficacious as I at first expected, and I then began to think of stirring up the subsoil, which gave rise to the idea of a subsoil plough. I thought I must construct an instrument which would execute the work with the least possible power. I made my plough very strong, and of that form to which the least resistance would be opposed, at the same time taking care to have sufficient power fairly to stir up the soil.

I will here explain the principle of the subsoil plough, because I have found that many persons, although seemingly acquainted with it, have not the proper notion of the principle on which it is based. The great principle is, that there are many subsoils, which, though capable of being converted into a good soil, yet if brought up and mixed with the active soil, will so far deteriorate it as to make it for some time sterile. It therefore occurred to me that the great point would be to stir up the subsoil, still retaining the good soil on the surface. Stirring up the subsoil would, in the first place, very much facilitate the escape of the water into the drains; and secondly, in consequence of the passage of the water through the stirred up subsoil and the attendant admission of air, it would be so acted upon as to be converted into good soil, while at the same time I was having all the advantages of working the active soil as before.

Upon the application of this principle, I found that which I had supposed before was right, and I have been successful in every instance in which I have tried it. The process of applying the subsoil plough is this; a common plough goes along first, and removes a furrow of the active soil. After that the subsoil plough passes along below, and scarifies the soil to the depth of from twelve to sixteen inches, in some instances eighteen inches. This is continued furrow after furrow, the plough going first to lay the active soil on the part already opened up; then the plough comes a second time and takes off a furrow from another part of the soil, and places it on that part which is already scarified.

Much has been said with regard to the proper period for applying the subsoil plough, some conceiving that it should be applied immediately, and others, at some period after the drains have been out. I think that in places where the drains have much effect, the subsoil plough may be applied the following year; but in clay soils it is of great importance to give the clay sufficient time to dry, and to have it in a sort of friable state; because, in the application of the subsoil plough, when clay subsoil has been recently drained, and it is not sufficiently dry, more harm is done than good; the clay being worked in a wet state is almost prepared for making bricks; and if we once work it in that state it is a long period before it recovers its friable property again. Therefore, I should say that in soils rather free, the subsoil plough may be used the second year after the drainage.

The proper time to execute drains is in the summer season, because you can then get it much more tidily done, and the drains are prevented from running; because in many places there are little sandy veins and portions of running sand, which are very apt to fall in before the drains are covered up. In the winter season this is almost sure to be so; and another disadvantage is, that you may be taken with frost, which draws off the adhesion of the earth, so that it falls down, and fills up the drain. It is best also to execute them in grass land before it is broken up for cropping, because otherwise it is much too soft. Executing it therefore in the summer season on the lee produces very little loss indeed, because you find that the growth of the grass in the after part of the season will be so much increased by the execution of the drains, that you will be repaid for the time lost for the use of the pasture during the time the drains were in process of execution. After the drains have been completed, I would recommend you to take a crop from the land, and if the land has been pretty good, it will, perhaps, afford two crops; at all events, one crop should be taken; and that will pass over one summer before the subsoil is to be ploughed. During this season the earth between the two surfaces has time to dry; it is much more friable, and the subsoil plough will be much more efficacious in stirring it up. Besides, it often happens that there are stones in the soil, which of course, must be removed before you can proceed with good husbandry; and it will be found that, in consequence of the contraction of the soil, they have become in some degree loose, and will be turned out very easily by the subsoil plough. In many instances we have stones exceeding 200lb. weight, which are turned out very easily by the subsoil plough with four horses.

With regard to the direction in which the subsoiling ought to be carried, I should say decidedly at right angles with the drains, because you thereby form channels, from the centre to the side, in all directions. In that manner you form artificial channels from the very centre of the ridge into the drain

and, although these may partially close up, still there is an openness given to the subsoil, which will permit the water to pass freely.

Having thus applied the subsoil plough to stir up the subsoil, the after cultivation may be the common rotation of the country, such as the farmer thinks suitable to the soil. But one thing which I would very much recommend is, that when agriculturists have subsoiled their land, they should follow the practice of laying down the land flat on the surface, without any ridges or furrows. There is nothing more injurious to the land than ridging it up. In the old modes of draining, it was quite necessary to have ridges and furrows; but now, when land is thoroughly drained, there is no occasion for it, and indeed it is hurtful; because when water falls on a rounded off surface, it immediately begins to sink away to the lower level, and the water which has fallen on the tops and middle parts of the ridges is added to the water on the side, which thus has to bear a great deal more than its own proportion of the water; the water carries portions of the soil along with it, and the cracks are constantly filling up by the running of the sand from the higher part of the ridge to the lower part. It must be obvious to everyone that when a field is laid down with ridges and furrows, especially on stiff land, a great part of the very best of the land runs down into those furrows, and is deposited in large quantities at the bottom of the ridge, thereby doing a great quantity of material mischief. If it is laid in a flat form, you get rid of this great evil, and obtain this advantage—that if the water is beneficial to the soil, which it certainly is, you have that benefit equally distributed; every part receives its own water, and receives the benefit which the water can give.

It is the suggestion of scientific gentlemen who have turned their attention to the subject of agricultural chemistry, that the rain in falling from the atmosphere absorbs a considerable quantity of ammonia; and if there is any affinity in the soil for ammonia, if the soil wants ammonia, the affinity will extract the ammonia from the water, the ammonia remaining in the soil for the nourishment of plants. It is also known, that where artificial manure is put into the soil, some of the fibrous parts of it will be carried away with the water, and be carried down to the region to which it belongs; and although not so near the surface as it was before, it is near enough for the plants to reach it when they put down their roots.

A very peculiar change takes place in any subsoil—it does not matter what composed of—after it is ploughed. This change begins to take place immediately, and the soil gradually goes from the state in which it was before to that of a mould. If you examine an oil which has become mould, it is of a very peculiar structure. It appears as if all the particles were connected together, and it seems to have some sort of attractive property by gathering together in that way. Vacuities for the air are thus formed, and there is a great tendency to absorb and retain as much moisture as is useful to the plant. If it is filled entirely with moisture it is injurious to the plant, but if there is a certain quantity, it becomes beneficial; and when a great depth of soil is attained, there is great advantage indeed, in anticipation of either a wet season or a dry one. In a wet season the water flows away, leaving the soil in a dry state; but in consequence of the mouldering state in which the soil is, it is very retentive of moisture, and there is a great magazine of water preserved in soil for a dry season. Being covered by the active soil, the drought may penetrate a few inches, but in consequence of the lower part of the soil being covered with this upper stratum, it is defended from the extreme action of the rain and a very dry atmosphere; consequently it will be found that in soil so treated and converted into this mouldy condition, in very dry seasons a sufficient quantity of moisture will be retained for the use of the plants, which will grow vigorously when land in the same neighbourhood is completely dry.

A notion has prevailed with some people, that it is possible to drain land too much. I do not think so, from the fact that the mould becomes an excellent magazine for the retention of moisture. A circumstance took place in regard to this in my own district, in 1826, a very dry season. In that year there was such a long period of dry weather that the pond was dried up, and there was a great deficiency of crops. I had a field which had been treated in the way I have explained, and I had a crop of hay on it. The hay in the country round was very poor indeed, producing not above half a crop. On this field, which I had deepened to 16 inches, I had a very splendid crop. A proprietor of land in the neighbourhood, one of the old school, resisted to the utmost of his conviction with regard to the result of thorough draining and subsoil ploughing. A person occasionally employed by me was also engaged in doing work for him. He had asked about this hay, and the old gentleman was rather puzzled at the state of the crop, and exclaimed that he really thought I had drained the land so much that I should have no crop at all. He was immediately after this completely wedded to the system, and from that day has been vigorously engaged in introducing thorough draining and subsoiling all over his estate; and he is now having a great deal of poor soil, on a very rich and productive estate, treated in the same way. Taking the average of that gentleman's estate, I should say that he now produces double the quantity of corn that he used to obtain. He now

grows potatoes where he could not grow them before, and on the old clay he produces regular and large crops of turnips.

A Gentleman inquired whether there was any land where subsoil-ploughing would be successful without thorough draining.

Mr. Smith—I am much obliged for that hint. Many persons have thought that ploughing the subsoil might do without draining, but there are few instances indeed in which that application of the plough will not be hurtful instead of being beneficial. If you have a retentive bottom which will not allow the moisture to pass away, it must remain till absorbed by the atmosphere; therefore the greater the chambers for receiving rain, so much the longer will the land be kept in a wet state. The practice which now prevails in the English clay districts of ploughing with a shallow harrow, has arisen from the experience of ages, which has taught them that on such soils you cannot cultivate wheat if you plough a deep furrow, because you make just so much the larger chambers to receive water. Even in open soils I would not recommend the application of the subsoil plough till the thorough draining has been executed.

A gentleman asked if it was necessary to repeat the subsoil ploughing.

Mr. Smith—It may not be essentially necessary to repeat it, but it is very beneficial. The practice I have adopted is to repeat the ploughing at every shift, every time I break up my fallow.

Another gentleman inquired if it was always done in the same line.

Mr. Smith—Generally; sometimes I have done it obliquely.

Did you ever try it diagonally?

Mr. Smith—Yes; and perhaps it is better to do it in that way according to the drop of the land. The first idea I had was to use the subsoil plough; then I thought I might use the trench plough, and that I might, the next shift, turn up the whole soil, so as to have a complete mixture. In some fields, where the soil was of better quality, and there was more vegetable matter, I had excellent crops; but, on the poorer soils, I found that by bringing up the subsoil to mix with the active soil, after the first shift, I did a great deal of mischief. I found, especially with regard to grass, that I could not get that growth of plants which I had before; and immediately on observing that, I resolved a third time to go over those fields, and that I would again use the subsoil plough: I have now fallen into the practice of doing so every time I turn. I took up at the first shift, perhaps about three inches, even in the poorest field; the next time three inches more; and by that means I gradually attained a thorough depth of soil to the extent of sixteen inches. On my own farm I have mentioned that I have a thorough depth of sixteen inches, but that is in consequence of using a trench plough on the second shift; and in some fields that was unsuccessful. If I had had then the experience I now have, I would from the beginning use the subsoil plough at each shift; and instead of going down the whole sixteen inches, I would only take up perhaps three inches the first time and three the next, till I had completed the depth of sixteen inches.

The lecturer was asked if he had ever used lumps of burnt clay.

Mr. Smith—I have seen it done, and it has been pretty successful, but there is considerable difficulty in the manufacture.

A Gentleman—As regards draining in the summer season, how do you get the level?

Mr. Smith—By the spirit-level, of course.

A Gentleman—The great object would be to get it done cheap; but it would be much more expensive if done in the summer.

Mr. Smith—No doubt; but if I had the choice of executing drains during the winter, at an expense of 50 per cent less than the summer, I would prefer doing it in summer. The efficiency is of far more importance than the expense.

A Gentleman objected, that in summer sometimes the land was too hard.

Mr. Smith—That may be the case in some places, but the great bulk of the land will retain as much moisture as will enable you to get through it with the plough. Of course that will be subject to variation in different parts of the country. In some places it had better be done when the ground is more moist. Still, I would recommend it to be done, not in the winter, but in the spring or autumn.

A Gentleman—I may perhaps be allowed to say that there are cases where subsoil ploughing is effective without thorough draining—as, for instance, in the soils of the moorlands. I have tried it myself in the moorlands, and have found that by simply breaking up that pan which holds up the water which made the lands dry in summer, and wet in winter, all the water escaped; and land before not worth 5s. an acre, let for 20s. after it was done. That was certainly a peculiar case.

A gentleman inquired whether the rocks under the stratification were horizontal or perpendicular.

Mr. Smith—There was very little stratification [at all. I am perfectly aware of what has been stated with regard to destroying the pans, such as are placed upon gravel; and though in the gravel the opening must be at a considerable distance, and consequently the water will be long in finding its way out, if it gets into the channel, it will go off easily. These dry soils

retain moisture a great deal too long for agricultural purposes. A neighbour of mine was draining his land—a sort of irregular subsoil—and in some places had very considerable ruts or rising ground, with sandy or gravel bottom: he instructed his steward to stop the drain when he came to those holes. This was done, and two winters after the gentleman was coursing, one day, and all at once his horse sank over the fetlocks in the soft ground. He called out to his steward to show the cause, and his steward explained that this was the portion of land on which he had desired the drain to be stopped. I mention this fact to illustrate what I have said, that when agriculturists determine on draining a field, they should resolve to drain it wholly, otherwise they are only throwing the expense away. I have seen instances where persons have drained wet parts, and left what they considered dry undrained. They very soon found that the land which was formerly the wettest, was then driest, and that when the part which had been drained was ready to receive the seed, they were delayed a few days till the other portion was sufficiently dry. In a country such as ours, where we have much changeable weather, all agriculturists know the advantage of a single day. Now, if a field is uniformly drained all over, you will perhaps be able to sow your seed one, two, three, or four days earlier than if it were not drained; sometimes now you lose the opportunity altogether, because it frequently happens that two or three days intervene; very newly-dried will be ready for being sown, whereas other land which was not drained would require a week or fortnight before you could sow it.

With regard to the application of thorough draining on porous bottoms, no doubt much good will be effected without subsoil ploughing. I have found it most efficacious on sandy and gravel bottom. Many persons think that by so doing mischief would result; but I have known instances of land of that nature being very greatly improved after being stirred up by the application of the subsoil plough.

A Gentleman—Your observations apply to thorough draining; many people call it furrow draining. I wish to know whether you have any reference, to deep draining, and how, as in the case of a spring lying deep, you meet the difficulty occasioned by the water. Two feet and a half drains would not touch a spring such as that described on the diagram. How do you get away the spring water,

Mr. Smith—They are called furrow drains, because they are made in the furrows. I call it the mode of thorough draining. I use the term to express the result. They are called sometimes wedge drains, top drains, and tile drains; but the principle is, that you have the drains sufficiently close together to carry off the water quickly; and then, that the best mode of laying them off for that purpose is to arrange them in parallel lines, and carry them as much as possible in the sloping direction of the land.

With regard to springs, the spring water can do no harm till it enters the subsoil; so long as it keeps below that, you need not care about it. The moment it reaches the bottom of the drain, it finds its way into it, and will be carried off by it. I have found it necessary, sometimes, to carry a drain through the eye of the spring. Springs sometimes come in little channels, at other times in a sheet, according to the nature of the subsoil. When they come in a sheet, the cross cutting completely scarifies them. If a spring comes out at a round opening and happens to fall in between two drains, I have found it necessary to cut the drain into the eye of the spring. But in every instance where the water flows between two beds, I have found that, by cutting the drain across, it was completely cut off.

I will now describe to you the mode of constructing the draining tile of Lord James Hay. One way of doing it is to construct the tile on the ground, and then carefully place it in the drain. The other is to execute it in the drain as you go along, and immediately to cover it up. The composition of the tile may be varied considerably, but the proportions which I have found to do very well are—

Lime	1 part	Blackened cinders	$\frac{1}{2}$ part
Sharp fine sand	3 parts	Gravel	3 parts

making altogether $7\frac{1}{2}$ parts, or 1 measure of lime to $6\frac{1}{2}$ of sand and gravel; the cinders may either be used or not. The gravel selected should not be of a large size.

[Mr. Smith then exhibited the manner of forming the tiles on the ground near the spot where they are to be used. The machine consisted simply of a large box, in the bottom of which were placed the moulds and cores, the box having at each end holes corresponding with the size of the cores at which to draw them out. The moulds being placed in the box, the box was closely filled with the concrete, which was firmly beaten down, and then the substance to form each tile was compressed by instruments adapted to the length of the tile. The cores were then drawn, the moulds and box lifted, and the tiles left behind, requiring only drying in order to be fit for use.]

Mr. Smith continued—

In our district lime is very dear; it costs about £1 per ton in the shell. The cost will be—

One ton of lime . . .	£1 0 0
Half ton of cinders . . .	0 1 0
Four tons of sand . . .	0 4 0
Two tons of gravel . . .	0 5 6
Grinding . . .	0 2 6
Workmanship . . .	0 10 0
	£2 3 0

These quantities will make 2880 tiles, which will be about the rate of 15s. per thousand. I would recommend in all cases that the gravel and the sand should be ground together, as thereby the lime goes much farther. By grinding them, also, in a wet state, they are better prepared to make the mixture which forms the concrete.

A question has been handed to me, as follows:—"What effect have thorough draining and subsoil ploughing on the habit of throwing out the wheat plant by frost?" There is no difficulty in answering this; because it is well known to be owing to the moisture that the wheat plant is thrown out, and whatever removes the moisture, will have the favourable tendency required. I have known many places where almost every winter the greater part of the plants were thrown out. Now, the result of thorough draining and subsoil ploughing is, that they retain the plant perfectly well, and have very abundant crops.

The best of the two modes which I mentioned of forming the tiles, is to make them just where the drain is wanted, and in a few days they will become so dry that they can be placed in the drain. One disadvantage is, that these tiles will not stand carting for a length of time. They require several months before they will admit of being laid one over the other. But, in most instances, the making of the tiles can be accomplished on the spot, and in the course of a few days they may be put into the drain. It is, then, of great importance to cover them immediately with some light soil, free from stones, and to beat them down so as to preserve it from injury. If there are any stones in the soil, they may get down to the tile and seriously injure it.

This is an instrument with which to form the tile in the drains.

[The lecturer then exhibited the method of forming the tiles in the drains, which is done by placing the mould in the place in the drain to be occupied by the tile, then laying upon it the concrete, and after pressure by an instrument similar to that used in the former process, drawing out the mould by means of a long handle attached to it for that purpose.]

Mr. Smith—With reference to the tiles, I would remark that it is better to make them in moist weather than in dry.

A gentleman inquired how long it would be before the drain could be filled in.

Mr. Smith—I consider it completed when the soil is put over the drain. In an experiment which I made in Forfarshire, as soon as the core had been withdrawn, when the soft soil had been beaten over the concrete, it was fit to be walked over in two days after. Having no greater covering than that on it, I jumped myself on the tile from the surface, without doing any injury, so that I consider beating the earth over the tile perfectly secures it from injury, and the moment it is completed it is beyond any danger—one day, at least, after the core is withdrawn.

A Gentleman—If I understood Lord James Hay right, he said it is better not to let the water run through immediately.

Mr. Smith—I should say that precaution was quite necessary; there would be some risk of the lower part being washed and injured. Mr. Littledale, of Cheshire, has also made experiments on the system. I cannot catch his eye, and therefore do not suppose he is here, or he would bear testimony to the advantages of it. The old mode is to have narrow ridges not more than three yards broad, because otherwise there would be no crop at all. There is generally a fringe like a bristle at the top of the ridge, and there is nothing in the furrow below. There is a gentleman who has followed the plan of thorough draining and subsoil ploughing, and has laid down his land flat; and he has succeeded in converting a very sterile clay into a clay which has borne a very splendid crop of potatoes, which he has sold this season for 40l. an acre.

I have an interesting communication to-day from Scotland, which, though not immediately connected with the subject before us, bears intimately upon it. There are great doubts respecting the propriety of putting seed deep into the soil, or covering it very lightly. Experiments have been made on that subject, but none so conclusively as that which I have now before me, which relates to the springing up of the more tender seeds, the grass seeds; and it shows the great importance of having a shallow covering over them. This experiment was made by the Messrs. Drummond, of Stirling, the individuals who first introduced the agricultural museums.

This experiment tends to show the great importance of a light covering to grass seeds. I have made a harrow of peculiar construction, which reduces the surface soil very much without tearing up the ground. It has no teeth, but acts by little sharp discs, closely set together, which curve very slightly. I have found this instrument also very efficacious if used as a brush harrow.

A great many questions have been put to me in the course of the lecture, which I have endeavoured to answer as satisfactorily as I could. I now take the liberty of referring to two gentlemen, who have had opportunities of seeing what has been done by the application of thorough draining and subsoil ploughing. One of these gentlemen is well known as an eminently scientific man, who has visited my farm, and has obtained information as to what it was in its original state, and to what it has attained by cultivation; I mean Dr. Buckland.

DR. BUCKLAND—Gentlemen, I am one, I believe, of the few individuals present who have had the opportunity of visiting the scene of these most interesting experiments. I believe the term Dean-stoning has been applied to the process, but "thorough draining" is the designation given to it by Mr. Smith. Every word uttered by Mr. Smith I can verify from my own personal inspection of his farm. I went there disposed to criticise, and there is but one attempt at criticism that I can offer on all I have heard or seen of Mr. Smith; and that is, that he talked just now of making straight lines round the hill. There may be a rule for doing that in Scotland, but it is at present unknown in this part of the empire. I can find no other fault, and I think that what I have said is the greatest compliment I can pay Mr. Smith. I examined the pond which has been spoken of, and I could find nothing there which indicated the presence of earth. Therefore it is quite clear that there is no tendency by any natural process to fill up those drains. A most important point is the total absence of furrows—an advantage which was not so fully pointed out as it might have been. The wetting which you have in the gutter, and the too great dryness which you have on the upper part of the furrow which you have in an ordinary field are avoided, and a healthy condition is assumed over the whole field, whether one or one hundred acres. One fact is better than any criticism which I can offer. On my return I visited Sir Robert Peel, and was conducted by him to see the worst farm on his estate. One of the fields which should have had grass upon it consisted in three-fourths of it of burnt clay, and one half was full of little plashees, which the tenant had covered with rotten dung. It was impossible that the moisture flowing from this could go down; it therefore began to dry, and its whole virtue was going to the wind. Sir Robert admitted the badness of the tenant, and promised to adopt the system I had recommended in one of my pamphlets. I heard no more of the matter till about the end of last autumn, and then I received a letter, which stated that Sir Robert had obtained possession of the farm, and was proceeding to drain it in the manner recommended by Mr. Smith. I hold it very important to get another experiment made in the west of England. I saw—and this shows the connexion of geology with agriculture—what the original condition of the soil was, as there is a small fragment of it over the hedge. Mr. Smith's soil is more than a foot deep, while over the hedge it is not more than three or four inches of the coarsest soil, not worth more than half-a-crown an acre; the value of Mr. Smith's I will not mention, but perhaps 3l. or 4l. an acre would be a fair guess. Now, Sir Robert Peel has in one year wholly changed this by improving the subsoil; and you shall hear the result sent to Sir Robert by his bailiff, to be transmitted to Mr. Smith. After the land had been drained on Mr. Smith's plan, it was limed with four tons of good lime per acre; it was then ridged up, the ridges afterwards split, and rotten dung put between. It was immediately moulded up, and the seed drilled on the ridge over the dung, so that the seed had the benefit of the dung at the first stage of vegetation. The first crop of turnips produced was four times greater than any crop produced on the same field at any previous time. The manure was good farm-made stable manure and farm-yard dung mixed; the proportion was 12 tons an acre; the best crop was 27 tons an acre; the seed (the Herefordshire white) was sown the 21st of June. The second best (26 tons) was red giant, sown the 23rd of June; the next was red top, sown the 24th of June; and the next the white globe, sown the 25th of June. The whole of the seed was from Skirving's, of Liverpool, and 2½lb. per acre was sown; the ridges were 24 inches distant from each other. That document was signed by Thomas Hill, Sir Robert Peel's bailiff. This is the result of twelve months' experience only, for Sir Robert Peel wrote to me, and said he sowed under unfavourable circumstances, and his neighbours were laughing him to scorn. Whether or not 26 or 27 tons of turnips an acre is a failure, on land which never before produced 6 tons an acre, it is for you to judge. Here is the whole expense repaid in the first year, and the land for ever worth forty shillings an acre.

A gentleman from Berkshire, who had cultivated a portion of Bagshot Heath, spoke highly in favour of Mr. Smith's system, and alluded to that gentleman as having almost taught him the rudiments of agriculture.

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.

SECOND COURSE—LECTURE XII.—RAILWAY ESTIMATES.

This lecture had reference to the consideration of estimates, as applied to railways—that is, to ascertain lineal dimensions, superficies, and cubic contents, and, affixing the proper rateable prices, to work out the monied results. The Professor said, that, probably, the most ready way to give a general idea on this subject would be to go briefly over the several heads to be considered in framing an estimate. It was assumed that proper plans and sections of the work had been prepared in a skillful manner beforehand, Mr. Vignoles strongly insisting on the necessity and importance of having all such documents furnished on a much larger scale, and with vastly more attention to accuracy and detail, than had often hitherto been the case, particularly for Parliamentary estimates, observing, that erroneous data and calculations could not but result from a neglect of this rule: and, he stated, that, although many of the standing orders of Parliament were annoying in some respects, yet the principle on which they were framed, went to compel a compliance with forms, in doing which, greater previous investigation and accuracy of plans and sections, became absolutely indispensable.

The quantity of land required formed naturally the first item of an estimate. It was but seldom, indeed, that the very small economy of taking land for one line of railway only was adopted. To a given breadth, therefore, for a double line—say, from eight to ten yards—must be added the necessary allowance for fencing and ditching—say, three yards on each side—making a constant breadth of fourteen to sixteen yards of land throughout, independent of the necessary slopes in excavations and embankments; the additional quantity for these, depends, of course, on the depth of the cutting, or height of the bank, in the various places, and on the ratio of the slopes of the earthwork. Suppose, in a cutting or banking of ten feet, this ratio to be one horizontal to one perpendicular, then, such slopes of one to one require ten feet additional breadth of land on each side—together, twenty feet—viz., twice the depth or height to be added as a further breadth, beyond the constant one for the railway and fencing. In like manner, for slopes of one and a half, two, two and a half, or three to one respectively, multiply the varying depths or heights of cutting or embanking by three, four, five or six, as the case may be, for the necessary augmented breadth of land due to the slopes, along their several extents; and thus, from the lengths measured, and the heights figured, on the section, the varying quantities of land are obtained, multiplying length by breadth, and reducing the areas to acres and parts for agricultural districts, and to square yards for land in towns and their immediate vicinities. For the prices to be assigned to these superficial quantities, the engineer must depend on the land valuer, who is also to judge of the amount of contingent damages. On an average, the actual quantity of land for a double line of railway, including the slopes of earthwork, may be taken at ten acres to the mile, but the precise areas must be ascertained in detail in the way explained. The cost of land for many of the leading lines of railway had been as much as £5000 per mile for the whole of their length. The cost of land for lines at a greater distance from the metropolis was less—still, from the numerous contingent after-charges, in respect of land, the sums were large, and had often far exceeded the original estimates.

The fencing of the land comes within the province of the engineer, though it is sometimes comprised in the item of land. The mode of fencing must always be regulated upon the custom and materials of the country. Dry-stone walls, earth mounds with furze hedges, posts and rails, quickset hedges, and broad side-ditches or drains, are the principal kinds of fencing through agricultural lands; walls of brick or masonry, set in mortar, are generally called for through towns or building land. The several lengths of each of these are ascertained from the plans; the prices are obtained in the localities. Including farm gates, the cost of fencing varies from 1s. 6d. to 3s. per yard lineal in the country. In the vicinity of towns, for stations, &c., the price will vary from 5s. up to 10s. per yard, according to circumstances, which it must be the business of the engineer to ascertain.

The third item is usually that of *Earthwork*—that is, to reduce the undulating natural surface of the ground to the railway level or gradient, by cutting through hills, and filling across valleys. Mr. Vignoles having, in the first course, entered at large into the consideration of earthwork, thought it unnecessary to say much here. The price of the earthwork depends abstractedly on the average work that an able-bodied man can perform in a day, in various soils—this it should be the study of the engineer to determine. The mere price to the workman, for getting and filling, may be taken at from 2d. to 5d. per cubic yard, for the various kinds of sands, gravels, or clays; and from 6d. to 2s. for harder materials, rock, &c., but, in addition, various other matters are to be provided—barrows, planks, wagons, temporary railways, &c.—the present modern practice in moving large quantities of earth is vastly different to what it was in this country thirty years ago,

or to what it still is on the continent, more particularly in the greater distance to which the material is carried; these several distances between the excavations and the points of depositing them, either into embankment or to spoil, must be ascertained from the longitudinal section, and a careful examination on the ground—these distances are technically called *the lead*; for distances under a quarter of a mile, the prices are higher, in proportion, than for longer distances. Taking the average description of soils, and the average distances, 1s. per cubic yard may be taken as a covering first estimate, upon the whole number of cubic yards of excavation or of embankment, whichever may be the larger quantity shown upon the section. The quantities of earthwork in a railway, on an average per mile throughout the whole distance, might be taken as a characteristic of its cost, so far as mere construction went, independent of carrying establishments, stations, and land, over which items the engineers seldom had control. Mr. Vignoles said it would be very interesting to have an abstract of the quantities and cost of the earthwork, distances carried, &c., on all the railways, and indeed, of all the other items of the works, as actually executed; they would become valuable precedents for future estimates, particularly if accompanied by explanations of the circumstances under which the operations were carried on. The great haste with which many of the railways were executed, while the late powerful excitement lasted, had added greatly to the cost, by raising the price of labour. Mr. Vignoles stated that he had already given some such abstracts of the railways that had been executed by him, or under his directions, and he was prepared to give more, and he hoped that other engineers would follow his example, as it could not but be very satisfactory to the proprietors of the different concerns, as well as a justification to the engineers themselves, and to the directors, that they could go into the minutest detail of expenditure. The Professor then gave abstracts, in round numbers, of the quantities of earthwork on many of the principal lines of railway, as well as could be ascertained from the sections. He mentioned the North Union Railway, twenty-one miles long, with 125,000 cubic yards of earthwork per mile, at an average cost of 10½d. per yard, including all extras and contingencies. The Midland Counties, 57½ miles, with 100,000 cubic yards of earth per mile, at an average cost of 13d. per yard, including slips and all charges, the soils nearly the same in each, and the average lead nearly alike—viz., one mile—attributing the difference to the great haste and great demand for labour in the latter. The mean of these would be now a fair estimate.

Having estimated for the cost of obtaining the artificial bed of the railway, the next item would be the *Bridging and Masonry*—that is, to restore the previously existing communications of roads, canals, or other railways, the passage of rivers, watercourses, &c., &c., by viaducts, aqueducts, ordinary bridges, culverts, drains, &c., and often by heavy retaining and breast walls. Under this head came the bridges of brick, timber, or iron;—in very marshy countries, where the foundations are likely to be bad, and the drainings liable to be affected, timber may be resorted to, and used in the shape of piling, with cross beams to sustain the rails across the openings, avoiding thus the cost of arches, abutments, and wing walls. The ascertainment of the several superficial or cubic quantities in each of these different constructions, is a matter of simple mensuration from the working drawings. The attachment of prices to these, in all their various details, with sufficient accuracy, depends on the mature judgment and experience of the engineer; and it is by a long course of careful study and observation that the young student, in his employer's office, and on his works, can alone hope to acquire this knowledge. It was but too common, in making estimates, to fall short in this item, particularly in the number of occupation bridges, which, owing to the complicated holdings, improvements, &c., had to be provided for to a vexatious extent, or bought off. The masonry is generally in proportion to the earthwork, and in many cases has happened to be of nearly the same amount of cost. The average number of bridges on a main line of railway might be taken at five for two miles. Diversions and embanked approaches of roads, gravelling or metalling the new surfaces, and the contingent operations, should be separately calculated. They are included under the head of fencing, of earthwork, or of bridging, or kept as a distinct item, according to the practice of the engineer, but they form a large sum, varying from 100l. to 500l. per mile, according to circumstances, and, in preliminary estimates, are too often omitted, or are put into that refuge for all deficient items—contingencies.

The item of *Upper-Works* in general, or *permanent way*, had been gone into so fully in the recent lectures, that it was not necessary here to do more than mention it, as forming a leading point in considering estimates. It is usual to add 10 per cent. upon all the items of the estimate, properly belonging to the engineer. Besides these were the preliminary expenses of surveys and Act of Parliament. The management, including cost of conveying, &c., and all salaries and expenses of direction, office, engineers, solicitors, &c., &c. Then came the expenditure on the stations, engines, carriages, repairing and building shops, fittings, and all the carrying establishment necessary for passengers, also for goods and for warehouses, wharfs, and other accommodation. It was in them the heavy extra expenditure of railway capital

mostly went, and which, in the early stages of the railway system, could no be properly judged of. By way of summary, Mr. Vignoles said he would give, in his next lecture, the actual cost of one or two lines of railway which had come under his direction, and which might be useful by way of reference in making out estimates on other occasions, though the construction and working of railways must be regulated on much more economical principles than had hitherto been the case, or no more of them would be undertaken.

LECTURE XIII.

In continuation of the observations on *Railway Estimates*, which had been commenced in the last lecture, Mr. Vignoles observed that, having therein gone fully into the items of *construction* of railways, he had only glanced at the very necessary provision to be made for the efficient *working* of them—viz., the *Stations and Carrying-establishment*, upon which he would say a few more words, for it was mostly under this head that the chief causes—or, rather, the chief excuses—for extra expenditure, or excess of estimates, had arisen. Properly speaking, this item, so costly, and yet so indispensable, should be taken as falling on a railway company, not as proprietors of the road, but as carriers—the distinction being, that if the railway was let on lease, as canals have been, or if everybody could carry on the railways, as they do on the canals—if, in short, public safety and public convenience, and generally necessary arrangements, did not make it imperative, or, at least, highly desirable, that the railway companies should be carriers (of passengers, at all events), the expense of stations and carrying establishment would not fall on them, though they must still be incurred by some parties, before the railway can be brought into profitable operation; nevertheless, the public, who are to use and be benefitted by the road, having, after all, to pay in one shape or another, are greatly interested in a proper expenditure, any excess of which is sure to be felt in increased charges or in diminished accommodation, until the grievous expenditure of a rival line is introduced. In analysing the cost of *Stations* it is obvious that the land always forms a prominent item, for, being near towns and populous places, it is to be bought by the yard, and not by the acre—building land, villa land, &c., &c., instead of mere fields. Hence, it will not be surprising, if it is found that the cost of the land, for the stations only, on many of the great lines, has amounted to as much as one-third of the whole cost of land for the railway. The *buildings* erected at stations may be divided into three classes—those for the accommodation of the passenger traffic—those for the goods, minerals, &c.—and those for the repair and maintenance of the engines, carriages, &c. At principal towns, therefore, large and distinct establishments must be erected; and, on long lines, a principal central depot for the engines, is often required in addition. At the minor and road stations the whole may be grouped together under one roof. In no department of expenditure have so many differences, and so much useless extravagance in construction and arrangement, been displayed, as in the buildings at stations; and hundreds of thousands of pounds have been absolutely thrown away from want of sufficient forethought and consideration, and by erecting enormous masses of buildings, either at the wrong places or in an injudicious manner. It was better to wait until the character of the traffic was ascertained, before making such expensive permanent establishments, and then to increase the accommodation by degrees. As an example of a moderate expenditure under this head, Mr. Vignoles mentioned some particular instances, and went somewhat into detail. At the terminus of a railway in a manufacturing town, with 80,000 inhabitants, there had been an expenditure of £9,500. for the passenger buildings, sheds, &c., &c.; £5,500. for goods' warehouses; about £2000. for the mineral traffic; and about £3000. for fixtures, turn-plates, &c.—say, in all, about £20,000. exclusive of the land, which had amounted to a very large sum, upwards of £13,000., including a good deal of spare space, existing buildings, &c., &c. At a smaller town on the line, but with some extent of goods' traffic, the cost for passenger buildings, sheds, &c., was £2500.; for merchandise accommodation, £3500.; turn-plates, fixtures, tools, &c., &c., £1000.; land about £3000. On the same railway the cost of six or seven various minor road stations, including water tanks, coke and engine sheds, tools, &c., was £3500.; land about £1500.; sundries on the whole line about £1000.—being a gross expenditure of £50,000. on station, land, and buildings, for a line of about twenty-two miles, which is at the rate of £2273. per mile; and the corresponding carrying establishment of engines, tenders, &c. (for passenger traffic only), was about £19,000.; for passenger carriages of three classes, horse-boxes, trucks, &c., &c., about £13,000. (the wagons for merchandise, coal, &c., as well as the engines, &c., being provided by carriers on the line, who provided their own carrying stock); and the necessary buildings for repair and maintenance of engines, carriages, &c., with tools, fixtures, &c. &c., about £12,000.—making a gross cost of £44,000., or £2000. per mile. The whole of this concern having been arranged with the strictest regard to economy, may be taken as a fair average, and it will be safe to say, that £4000. per mile for an effective carrying establishment, with the necessary stations, is a moderate sum. For lines of less traffic, if of considerable extent—as, for instance, say for some of the long lines from the present railway termini in the north of England, to

either of the principal towns in Scotland, a smaller amount might be sufficient; but Mr. Vignoles considered that it would be unwise to estimate a smaller expenditure than that of £3000. per mile for *Stations and Carrying-establishment*, on a line to be worked by locomotive engines, and it would be much safer to take £4000.; on either of these sums, £1500. per mile for the locomotive stock and buildings must always be estimated, and about £500. per mile for the carriage department—leaving from £1000. to £2000. per mile for the stations, according to the extent of accommodation; keeping the instances of the extraordinary outlay on some of the principal railway lines as examples to be avoided, and not to be imitated, or referred to, as necessary.

Under the last head of *Management*, came all the various and miscellaneous items of expenditure, between the first concoction of the project, to the closing of the capital account. The preliminary expenses of examining the ground, levelling, surveying, maps, &c., and all the formalities in the engineer's department, to enable application to be made to Parliament; the ascertainment of the traffic, revenue, travelling, and other expenses of various kinds, &c., &c., generally undertaken by the secretary; the valuation of land, &c., by the surveyor; the collections of the names of owners and occupiers, notices to them, applications for their assents, &c., and the management of the Bill throughout all its stages, falling to the charge of the solicitor. All these must be incurred before a spade was put into the ground, and had heretofore varied from £500. to £1000. per mile, according to the facilities afforded, the opposition encountered, the length of the line, &c. In future estimates, it was to be hoped this item might fairly be put, as not exceeding the smaller of these sums. Then came the setting out of the line, the detailed levels and surveys, and all the office work of the engineer, until the works are put into the hands of the contractor. The minute valuations of the property to be taken, and the juries, references, conveyancing, stamps, and all the various legal steps until the company are put into full possession. Then the office establishment for regulating all the financial and ministerial affairs, and the temporary arrangements, police, law suits, and legal and illegal charges of all kinds, taxes and rates, interest and commission to agents and brokers, travelling expenses, salaries, and a great variety of disbursements of a miscellaneous kind, which, in the aggregate amount to a large sum. The whole of the outlay thus coming under the head of *Management* has varied from 5 to 10 per cent. on the gross cost of the railways hitherto executed, according to their extent, and the amount of capital embarked, and especially according to the degree of vigilance exercised to keep down expenses, which depends chiefly on the director or secretary, or under whatever name the acting manager of the company may superintend. Judging from the examples past, and the deep impression which has been made on the public mind of the necessity of economy in every department, Mr. Vignoles thought 5 per cent. might be estimated hereafter, unless the lines were very short, and the capital small.

In recapitulation, the Professor observed, that the young engineer should always keep in view, for his estimates, the preceding great divisions of the cost—viz., *land*, including the damages, and fencing—*earthwork*—*works of art* (bridging, masonry, &c.)—*upper works* (the permanent railway proper)—*stations and carrying establishment*—*management*—and having, in his first estimates, allowed amply for each of those items under their several heads, he should add at least 10 per cent. for unforeseen contingencies. Some of the preceding items would be common to almost all railways, and others, of course, would vary greatly, according to local circumstances, chiefly regulated by the amount of earthwork; for, as that is heavy, so the works of art become costly, since the works of art are merely to restore the existing communications of the country, and the natural or artificial water-courses and drainage to their state before disturbed, or as near as may be, and that to an extent in exact proportion to the civilisation and improvement of the country, to enforce all which stringent clauses are inserted in the Acts of Parliament, and plenty of persons are always on the watch to enforce them. Mr. Vignoles observed, that the land, levelling of the ground, and restoring of communications, might, on the average, including contingencies, extra land, &c., be taken as forming about 50 per cent. on the total outlay of railways hitherto executed. But, referring to the items the Professor had gone over in detail in previous lectures, it appeared that, when proper economy and circumspection was used, the necessary cost of the railway proper—that is, the necessary quantity of land for the road only, a good substantial set of upper works for a double way, and a complete and effective carrying establishment—might, and had been, obtained for £10,000. per mile. All beyond is expenditure to obtain gradients, more or less perfect, and Mr. Vignoles thought that the great error all engineers had hitherto committed, the cardinal mistake—of which he himself was far from guiltless—was, seeking to make railways, intended, as they were, chiefly for passengers, *too perfect*—that is, of cutting down hills, and filling up valleys to too great an extent, on the erroneous supposition that the engines were always to carry *maximum* loads, which was very seldom the case, and never would be so on lines at a distance from the metropolis, particularly such as the lines into Scotland, previously mentioned. In short, the Professor in-

sisted that the engineer should, in such instances, and for the cross railways, which he yet hoped might be introduced, make the gradients and curves much less theoretically perfect; and that the amount of expenditure, beyond the above stated necessary one of £10,000. per mile, should be reduced to the very *minimum*; and he considered that henceforth an average of £15,000. or £16,000. per mile, and a *maximum* of £20,000., or, in very extraordinary cases, indeed, of £25,000., should be looked to for the construction of double lines of railway in any country, but that in most cases, of light traffic, and consequent adaptation of gradients, for single lines, a sum of from £7000. to £12,000. per mile would be the limit of total expenditure. Mr. Vignoles concluded by observing, that the preceding abstracts were deduced from very detailed accounts, which had been arranged on a uniform system, and kept from the very commencement of each undertaking, so as to be available, at any time during the progress of the works, to show the exact state of the expenditure; and had been finally worked out to the nearest thousand

pounds, as above. And the Professor expressed his great hope and expectation that this example would be followed, and that similar accounts would shortly be forthcoming, of the corresponding items of cost on all the principal railways in this and in other countries, more especially where complaints of improper excess of expenditure over estimates (well or ill-founded) had been charged, for the publication of such accounts—and the more in detail the better—would be the most complete defence of the directors, and the most satisfactory explanation from the engineer, and alike valuable, as statistical information, to the country—as salutary guidance to the capitalist and speculator—and as valuable information and warning to the old as well as to the young practitioner.

The preceding is a very brief outline of this interesting lecture, and the following, we believe, is a correct abstract of the cost of the two railways quoted by Mr. Vignoles.

Comparative Abstract of the Cost of two Principal Lines of Railway, under the general heads of Expenditure, as deduced from the very latest accounts of Actual Expenditure, brought out to the nearest round numbers:

MIDLAND COUNTIES RAILWAY. [57½ MILES.]				NORTH UNION RAILWAY [25 MILES.]				
Pr. cent whole cost.	Cost pr. Mile. £	Total Cost. £	— — —	Heads of expenditure.	— — —	Total Cost. £	Cost pr. Mile. £	Pr. cent whole cost.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ACADEMY OF SCIENCES.

June 20.—A paper by M. Vicat was read, "On the nature of Pouzzolanes." M. Vicat, having discovered the nature of the substance, has been able to compose a substitute with pure clay, calcined whilst exposed to a dead heat, so as to get rid of eight or nine-tenths of the water combined with it. The best clay for the purpose, says this gentleman, is pipe-clay; and in proportion with the admixture of iron, manganese, carbonate of lime or sand, is the defect of quality.

M. Degoussé gave an account of some recent results in the making of *Artesian wells*. He states that he has bored for water in the plateau which extends from Lagny to the forest of Arminvilliers, at the height of 110 metres above the Marne. In one spot an abundant supply of water rushed out, although he had gone to a depth of only nine metres. With M. Degoussé's report he forwarded to the Academy a letter which he had received from Aimé-Bey, the director of the mines of Egypt, who announces his intention of re-opening some of the bored wells of the ancients, at the foot of the Libyan chain, and requests that the necessary instruments may be sent out to him for that purpose.

June 27.—A paper on the effect of oil in calming the waves of the sea. By M. Van Beck.—M. Van Beck thinks, with Franklin, that the phenomenon may be explained by admitting that there exists between air and water a certain natural affinity or adhesion. Water, he says, takes in with avidity the air with which it comes in contact, so that it is with difficulty expelled. It results that, whilst a current of air passes over the surface of the water, the air attaches itself to the liquid, and creates small waves, which, as the wind increases, become large and dangerous. As soon as these waves are covered with a membrane of oil, the adhesion of the air upon the water ceases to exist, and the surface is no longer disturbed.

A communication was read from M. Combes, on the *thermal springs of Hamam-Escouton*, on the Banks of the Raz-el-Akbar, in Algeria, about

thirty leagues from Bona. The waters of these springs, which rise in the midst of a plain from little conical domes formed by themselves, are sulphurous, and of the high temperature of 80° of Réaumur.

July 4.—A paper was read "On the Geological State of the southern part of Brazil, and on the Heavings-up of the Earth, which have at various periods changed the appearance of the country," by M. Pissis. The ground examined is situated between the 12th and 27th degrees of central latitude, and comprehends the space between Parana, San Francisco, and the sea. Three periods of rising or heaving up are perceptible in Brazil, the last belonging to the end of the tertiary period. The immersion of certain strata placed at the bottom of the province of Bahia, and a slight elevation of the table lands, found between the sea and San Francisco, have been the results of it.

"On the action exercised on the surface of various Liquids, by the influence of the Vapour of certain Substances, and by their immediate contact." By M. Dutrochet. Light bodies placed on the surface of the water are repelled to a certain distance by the vapour of camphor, of ether, or even of alcohol, and the essential oils. M. Dutrochet's experiments oppose the opinion hitherto received, that this phenomenon is due to the impulsion which results from the rapid expansion of the vapour, which, striking on those light bodies, produces the removal of all the liquids subjected to the experiments. Ether is the one which produces the most vigorous movement of light bodies placed on water, mercury, and several acids and alkalies, but the movement is not always a repulsion, and is subject to great variation. Thus the vapour of ether attracts flour of sulphur placed on the surface of sulphuric acid, and produces a repulsion on the surface of nitric acid. If water be added to these acids, the movement is weakened in proportion as the quantity of water is increased. M. Dutrochet attributes these different movements to a modification of capillary attraction. He observes that, in reality, there is neither attraction nor repulsion in the floating bodies, that their displacement impedes the current, of which the surface of the liquid is the seat, and which has its origin in the heaving up or depression below the liquid, which may be reduced to steam.

July 18.—A paper was read by M. Rameaux, of Strasburg, on the *vital heat of plants*. M. Rameaux has ascertained that the heat varies materially,

not only according to the external temperature, but also in the different portions of the plants. This he attributes to the flow of the sap, which, having received the vital heat from the direct action of the sun's rays, carries it as it flows; consequently, the portions immediately under the influence of the sap have a higher degree of temperature than those which are most distant.

Another report was made to the Academy, on the cuirass of cotton felt, as a means of defence in war. In the first report to the Academy, the conclusions of the commission were not altogether favourable; for, although it was admitted that the cuirass resisted the action of pistol balls, it bore traces of injury from the concussion to which it was exposed. In the present instance, it appears that the cuirass was exposed to a severe test, by being fired at with cavalry pistols, at the distance of a few paces, and that it effectually resisted the balls.

July 25.—A paper was read by M. Vallée, "On the mode of rendering the Lake of Geneva subsidiary to the Rhone." Amongst the phenomena presented by the Lake of Geneva is one which has particularly attracted the attention of M. Vallée, viz. the sudden changes of level which in the country are called *séches*. He attempts to account for this phenomenon by supposing the existence of a subterranean lake, communicating on the one side with the Lemman, and on the other with the high valleys by means of natural wells, which are nearly vertical. In this way he endeavours to explain the rising and falling of the waters at Geneva, which have been frequently noticed to vary as much as two metres at a time, and to account for the rapid and extensive changes which occur in the temperature of the lake.

August 1.—M. Bessel, of Königsberg, and Professor Erman, of Berlin, were present. Each read in French a communication to the Academy. The paper by M. Bessel was on the laws of atmospheric refraction as connected with astronomical observations. The paper by Prof. Erman was a report on a meteorological voyage of circumnavigation. In the course of M. Erman's expedition round the world, the vessel in which he was, passed four times from latitude 50° north to 58° south, and during this transition M. Erman made observations with the barometer six times a day. He states from them that, in general, the pressure on the barometer goes on diminishing very slowly from the equator to the poles, and what proves that this depends on the general constitution of the atmosphere, is the fact that the diminution is constant and regular. Thus in the waters of Cape Horn, as well as on the coasts of Kamschatka, the mean height of the barometer is twelve millimetres lower than the mean height of the great equinoctial ocean. Hence it follows, says M. Erman, that the pressure of the air is not the same on basins of the same level in vast seas. M. Erman concludes, from the result of his observations, that a hope may now be reasonably entertained of becoming fully acquainted with the general law of the distribution of the air over the surface of the globe, so far as that law may appear to depend on pressure.

A report was read by M. Dufrenoy, on a communication from M. Amédée Burat, respecting the position of the coal veins in the basin of the Saône-et-Loire. The veins are not in strata, and they exceed in thickness all others known, but the veins are less continuous than in other coal districts in their direction and inclination, are mixed with clay, and he concludes that they have been formed by a vegetation on the spot, periodically destroyed by the rising of the neighbouring waters beyond their ordinary level.

Aug. 8.—M. Arago gave an analysis of a paper by M. de Ruolz, on the means of firing one metal upon another by the galvanic process. When the first paper of M. de Ruolz, on this subject, was read, the practical use of the discovery had gone no further than the precipitation of pure metals, and it remained to be ascertained whether mixed metals could be precipitated. This M. de Ruolz has done, and several specimens covered with a precipitate of copper and tin, in the proportions which constitute bronze, were submitted to the Academy. The red tint of copper, so offensive to the eye in objects of art produced by the galvanic process, has given place to the more delicate and pleasing appearance of bronze. The various advantages of the galvanic system are fully shown in the paper of M. de Ruolz. A precipitated coating must always be more regular and uniform than one laid on by hand. It can be made to any degree of thickness, and cannot be detached from the material to which it is applied. Iron roofs, for instance, both as to frame-work and sheet-iron, may be coated so as to resist the action of the atmosphere, and this without any great augmentation of cost, for the coating may be thin, and the iron work itself, not being exposed to atmospheric action, may be made much lighter. For domestic purposes, the galvanic process as regards a leaden envelope, may be advantageously employed in various ways, and M. de Ruolz suggests that it would be well to employ it for iron shot, which undergoes great deterioration from exposure to the atmosphere.

A letter was read from M. Agassiz, who has been for some time encamped on the summit of the Aar, for the purpose of studying the phenomena of the glaciers. He writes that the mass of ice in that part advances towards the valley at the rate of 220 feet annually, and the surface loses 7 feet of ice every year, which loss, however, finds its compensation in the infiltrations which become frozen, and raise the base.

Aug. 15.—M. Dumas placed before the Academy some specimens of the power of the newly-invented roller, by M. Schatteamann, which, according to a former report, has been used with great effect in compressing together into one solid mass the fractured portions of the stones used for macadamizing roads. The specimens now submitted to the Academy are of two kinds. In

the one the interstices of stone are filled with sand, so compressed as to become as solid as the stone itself; in the other, fragments of stone are rolled together, and form the most complete cohesion.

Aug. 29.—A further communication was read from M. Agassiz. M. Agassiz informs the Academy that he has ascertained that the glacier is throughout mined and sapped by watercourses, as he was convinced, from experiments which he had before performed, and of which he had given an account, that ice is porous in a high degree, and that the motion of glaciers is due in part to the infiltrations of water through the mass, thus undermining the base; and that the experiments on the glacier of the Aar have established the truth of this theory. M. Agassiz also mentions a fact which tends to corroborate what has been stated as to the phosphorescence of clouds. He mentions that it is more easy, on the glaciers at night, to distinguish the hands of a watch when the sky is covered with clouds, than when it is cloudless and the light of the stars is seen. He also states that the appearance of a peculiar snow, well known to all visitors of the glaciers, is not a snow that falls, but merely a modification of the frozen surface.

In a paper lately read on some remarkable circumstances connected with the *Daguerrotypes*, it was stated that a cameo having been suspended so as to hang near, but not to touch, a polished plate in a box from which all light was excluded, the engraving of the cameo was clearly and distinctly marked on the plate. M. Breguet, the celebrated watchmaker, has addressed a letter to the Academy, in which he states that he has frequently seen, on the polished inner surface of the gold cases of his flat watches, the name of his house plainly and legibly marked, the impression having been received from the engraved letters of the covering of the works, which did not touch the case.

Sept. 5.—A communication was read from M. Vallé, a colour-maker, on the employment of a solution of caoutchouc for canvas used by painters. M. Vallé was led to the researches which have terminated in the invention which he has submitted to the Academy, by observing the injury caused to the works of some of the greatest masters by the influence of the atmosphere upon the canvas. M. Vallé's method of preparing the solution is at present a secret. Although applied to both sides of the canvas, it leaves it sufficiently elastic to prevent cracking, and secures it against the action of the atmosphere. To this discovery he adds that of a peculiar kind of varnish for the painting, and thus he defies the ravages of time.

The subject of the meteors commonly called shooting or falling stars, was alluded to. According to the last communications from M. Arago, the period between the 10th and 12th of August still retains a marked superiority for this phenomenon, which is still so little understood. M. Littrow, of Vienna, counted, on the night of the 10th of August, 129 of these meteors per hour. On the same night M. Bonard, of Rennes, counted 44 per hour; at Tours, and in the department of the Doubs, M. Laugier and M. Mauvais witnessed a shower of these meteors. At Paris and at Toulouse the observations of M. Eugène Bouvard and M. Petit were attended with less marked results, but still they were sufficient to prove that the period of the year above named is that in which the phenomenon abounds. In a communication to the Academy, M. Bourdot, of Grand-Lemps, in the Isère, states that he watched with great attention the passage of these meteors on the night of the 11th ult. In no instance, when they exploded, did he hear any noise, but the explosion was, in several instances, followed by a long train of phosphoric light.

INSTITUTION OF CIVIL ENGINEERS.

April 26.—The President in the Chair.

"A description of a new arrangement for raising Ships of all classes out of water for repair, proposed to replace the Graving Dock or the Patent Slip in certain situations; with observations upon the other methods used at different periods for this purpose." By Robert Mallet, M. Inst. C. E.

This communication describes an apparatus proposed by the author as a substitute for the graving dock or the patent slip, in situations where such constructions would be too expensive, or an inappropriate locality prevents their adoption. It reviews the principal methods hitherto in use—such as stranding by bilge-ways, careening or heeling over, lifting by the camel, the graving dock, the floating dock or caisson, the screw and the hydraulic docks (both American inventions), and Morton's patent slip; it enumerates the localities for which each of these inventions is most applicable, and then gives the objections to them. The author then describes the general principle of his invention to be, the diffusion of the load or strain over the greatest possible number of fixed points, avoiding casual and unequal strains; that there should be uniform motion, with a power proportioned to the resistance. In providing for this, the joggle-joint is used throughout. The machine consists of a platform, supported upon a series of frames with joints at each end, attached at the lower extremities to fixed points in the foundation, and at the upper ends to the under side of the platform, which is traversed by a series of beams, to the ends of which are fastened rods connected with rollers, working in grooves along a suspended railway on the cantilevers of two

jetties, which are built to form the sides of the apparatus. A chain connected with all these rollers traverses in each suspended railway groove, and the power of a steam-engine and wheel-work, being applied after the vessel is floated on the platform and made fast, the frames raise the platform and vessel together gradually out of the water, permitting free access all round the ship; and when the repairs are completed, the whole is again lowered into the water. It is contended that many practical advantages would arise from this system—that the ship would not be strained, that time would be gained, and that it is superior to the ordinary methods now practised. The calculations of the leverage, the division of the load over the fixed points, &c., are given in detail, and the paper is illustrated by a series of elaborate drawings and a complete model of the apparatus.

Remarks.—Mr. Rendel thought that credit was due to Mr. Mallet for the science and the practical skill combined in the production of the contrivance under discussion; it was perhaps imperfect in some of the details, but he was inclined to believe that, in certain situations, and for vessels of moderate size, it might be adopted. Its construction would certainly be more expensive than that of a patent slip, but it would be less costly than a graving dock, and not liable to injury from hydrostatic pressure, to guard against which frequently constituted a main portion of the expense of a graving dock. The foundation of this structure might be simple, as the weight was distributed over so many points; he conceived, however, that unless it was established where the rise of tide was considerable, the foundations must be laid at a depth of 5 or 6 feet under low-water mark, to allow for the thickness of the frames and the platform beneath the ship's bottom. He was of opinion that a modification of the plan might be advantageously employed for canal lifts.

Mr. Hawkins agreed with Mr. Mallet that a ship must be strained while on a patent slip, because the timbers were all bearing a weight at an angle; but more particularly when leaving the slip, as the stern floated whilst the stem was still on the cradle of the slip.

Mr. Palmer did not admit the advantages of the proposed plan over graving docks, for, as they are now constructed, they possess every requisite convenience for examining and repairing vessels; the gates are made to exclude the water perfectly, and the machinery for pumping is so effective, that a very short time suffices to lay the dock dry. The plan might possess some advantage over Morton's slip in retaining the vessel in a vertical position, but it would be more expensive to construct, and he was not at all convinced that the objections urged against the patent slip were well founded.

Mr. Gordon observed that the position of a ship upon a patent slip was exactly that in which it was built; he could not therefore understand why it should be so very injurious; besides, if the stern cradles were elevated, as was the case on some of the slips proposed by Captain Brown, the vessel remained nearly on an even keel. Another improvement introduced by Captain Brown was, substituting solid rollers for the wheels of Morton's slip, the axes of which frequently twisted and prevented the progress of the vessel. Among the modes of examining the bottoms of vessels enumerated by Mr. Mallet, he had omitted the "gridiron," which consisted of a strong frame of horizontal timbers resting upon the heads of piles a little above low-water mark; over this frame the vessel was moored, and on the tide receding was shored up, resting upon chocks. When it was dry the bottom could be examined, and any slight repair made before the returning tide floated the ship off. "Gridirons" existed at Liverpool, at Havre, and at many other ports.

The President observed, that, like the form of breakwaters, much depended upon locality. Where timber was cheap, and the rise of tide considerable, the plan might be applicable; at Liverpool, where the tide rose 30 feet, and in the Channel Islands, where the rise was 40 feet, the platform might be 10 feet above low-water mark, and still accommodate any ordinary vessel. It certainly appeared to avoid some of the main expenses of the graving dock, in which so many precautions must be taken for preventing the springs rising and blowing up the bottom. The Institution was much indebted to Mr. Mallet for the great pains he had bestowed on the communication, for the complete drawings and model illustrating it (which were presented to the Institution), and he deserved credit for the ingenuity displayed in the contrivance.

"Account of the Machinery and Apparatus for compressing and using Gas for Artificial Illumination at the Portable Gas Works of London, Edinburgh, Manchester, and Paris." By Charles Denroche, Grad. Inst. C. E.

This paper gives an account of the improvements introduced by Mr. David Gordon into the syphon forcing-pumps, reservoirs, &c., whereby the requisite degree of compression was obtained for rendering gas portable for the purposes of illumination, and of the arrangements adopted in the works at Edinburgh, Manchester, London, and Paris. A description is given of the various kinds of apparatus which were tried before a pressure could be obtained of 30 atmospheres, or 450 lb. per square inch. The portable lamps, with their ingeniously contrived graduated cocks are also described, with the several parts composing the apparatus. It appears that, owing to the cost of compression, which was 3s. 6d. per thousand cubic feet, and that of delivery, which amounted to 10s. per thousand cubic feet, the speculation was unsuccessful in a mercantile point of view, although most of the mechanical difficulties were overcome. The paper was accompanied by a series of detailed drawings of every part of the apparatus.

May 3.

"Description of the Tunnels, situated between Bristol and Bath, on the Great Western Railway, with the methods adopted for executing the works." By Charles Nixon, Assoc. Inst. C. E.

The works described in this paper comprised a large quantity of heavy earth-work in tunnels, &c.; they were commenced in the spring of the year 1836, and terminated in the year 1840. The whole of the tunnels are 30 ft. in height from the line of rails, and 30 feet in width; they are curved to a radius of about 120 chains; the gradient of that part of the line is 4 ft. per mile. The strata through which they were driven consisted generally of hard gray sandstone and shale, with the gray and dun shiver, &c.; in a few places only, the new red sandstone and red marl were traversed. Every precaution was taken for securing the roofs, by lining them with masonry where the nature of the strata demanded it, and in some places invert arches were turned beneath. Driftways were driven before the tunnels were commenced, and shafts were sunk to enable the work to proceed at several points simultaneously. The modes of conducting the works by these means are fully described, with all the difficulties that were encountered. The construction of the centres is given, with the manner of lining the arches with masonry, which is stated to be what was termed "coursed rubble;" but was of a very superior description, and in every respect similar to ashlar-work. The author offers some remarks with regard to the expense of working tunnels by means of centre driftways. He states this plan to be costly, and in many instances without corresponding advantages, on account of the difficulty of keeping the road clear for the wagons. He recommends that when driftways are used, they should be on the lower side of the dip of the strata, as the excavation would be facilitated, and the road would be kept clearer. In long tunnels he has found the cheapest and most expeditious mode of working to be by excavating the centre part from shafts, and both the ends (together if possible) from the extremities after the open cuttings are made. The drawing accompanying the paper gave a longitudinal section of all the tunnels, and showed to an enlarged scale several transverse sections of them, where the variations of the strata rendered either partial or entire lining necessary.

Remarks.—In answer to questions from Mr. Vignoles and other members, Mr. Nixon explained that the extra number of shafts had been required in order to enable the works to be completed within a given time; there had not been any accidents during his superintendence, but subsequently one of the shafts had collapsed. The cost of driving the driftways, the dimensions of which were 7 feet wide by 8 feet high, was ten guineas per yard lineal. He then described more fully his proposed plan of cutting the driftways on the lower side, instead of the centre of the tunnel, and stated the advantages chiefly to consist of a saving in labour and gunpowder, as a small charge sufficed to lift a considerable mass of rock when acting from the dip; the road was also less liable to be closed by the materials falling into it when the enlarged excavation proceeded from one side instead of upon both sides.

Dr. Buckland, after returning thanks for his election as an honorary member of the Institution, expressed his gratification at the prospect of a more intimate union between engineering and geology, which could not fail to be mutually beneficial, and cited examples of this useful co-operation in the cases of railway sections, and models that had recently been furnished by engineers to the Museum of Economic Geology. He then proceeded to remark upon the geological features of the South-Western Coal Field near Bristol and Bath, which had been described by Mr. Conybeare and himself, in the Transactions of the Geological Society of London (1824). Some of the tunnels near Bristol are driven in the Pennant Grit of the coal formation, where it is thrown up at a considerable angle, and composed of strata yielding slabs and blocks of hard sandstone used extensively for pavement. In traversing such inclined and dislocated strata, the engineer's attention should, he conceived, be especially directed to the original joints that intersect the beds nearly at right angles to their planes of stratification, and also to the fractures produced during the movements they have undergone. These natural divisions and partings render such inclined stratified rocks unworthy of confidence in the roof of any large tunnel, and liable to have masses suddenly detached. Inclined strata of a similar sandstone are perforated by many tunnels on the railway near Liège, in nearly all of which the roofs are supported by brick arches. It has been found impossible to make the tunnels through Lias and Red Marl without continuous arches of masonry. In any of the tunnels which have been carried through strata of the great oolite, the parts left unsupported by masonry would, in his opinion, be peculiarly liable to danger, because even the most compact beds of oolite are intersected at irregular intervals by loose joints at right angles to the planes of the strata, and occasionally by open cracks; and it is to be feared that the vibration caused by the railway carriages would tend eventually to loosen and detach these masses of stone. He apprehended still greater danger would exist in tunnels cut through the loosely jointed strata of chalk, unless they are lined throughout with strong masonry; and even that, in a recent case, had been burst through by the weight of the incumbent loose chalk coming suddenly upon the arch. In open cuttings through chalk, where the numerous interstices and the absence of alternating clay beds prevent any accumulation of water, there is little chance of such frequent landslips as occur where beds of stone, gravel, or sand rest on beds of clay; but until the side walls of chalk are reduced to a slope at which grass will grow, they will be subject to continual crumbling and the falling down of small fragments, severed by the continual expansion and contraction of the chalk, under the destructive force of atmospheric agents, and chiefly of frost. In open cuttings, where the

inclination of the strata is towards the line of rails, the slope should be made at a greater angle than if the strata inclined from the rails; if this be done, fewer landslips will occur from accumulations of water between the strata thus inclined towards the rails; and such slips may be further guarded against by minute and careful observation of the nature of the individual strata, and a scientific application of subterranean drains at the contact of each permeable stratum with a subjacent bed of clay. Tunnels can be safely formed without masonry in unstratified rocks of hard granite, porphyry, trap, &c., and in compact slate rocks; also in masses of tufa, such as cover Herculaneum, and are pierced by the grotto of Pausilippo near Naples; but in his opinion, wide tunnels driven in stratified rock could not be considered secure unless they were supported by arches.

Mr. Sopwith confirmed the remarks on the importance to the civil engineer of a knowledge of the geological character of the strata through which tunnels or open cuttings were to be made; the cost was materially affected, as well as the stability of the works. The angle of inclination and the lines of cleavage should be carefully studied; on one side of a cutting the slope might be left steep, and all would be firm and dry; whilst on the other, if the same slope was adopted, all would appear disintegrated and wet, and a series of accidents would be the necessary consequence. He could not sufficiently urge the importance of a more intimate connexion between the geologist and the engineer.

In answer to a remark by Mr. Farey on the apparent advantages of Frazer's centres for tunnelling, Mr. Bull promised to procure for the Institution an account of the execution of some work with them.

"An account of the Railroad constructing between Liège and Verviers, Belgium." By Lieutenant Oldfield, Assoc. Inst. C. E.

The materials for this communication were drawn from the memoranda made during a tour by the author, who is an engineer officer in the service of the East India Company. It describes the general course of the railway, descending by the long inclined planes, from the height above Liège to the valley of the Meuse, its progress along the banks of the Vesdre, through tunnels, and over almost innumerable bridges and viaducts, to Chaudfontaine, and thence onward through the town of Verviers, in the direction of Aix-la-Chapelle, to the frontiers of Germany. The modes of excavating the tunnels, and the materials used in the other works on the line, are accurately described; the general acclivities and curves of the road, the rails, chairs, and methods of fastening them to the sleepers, and the prices of labour and materials, are all given in detail, and the whole was illustrated by enlarged diagrams from the author's sketches.

May 10.—The PRESIDENT in the Chair.

"Description of a Flax Mill recently erected by Messrs. Marshall and Co. at Leeds." By James Combe, Assoc. Inst. C. E.

The mill described in this communication consists of one room, 396 feet long by 216 feet wide, covering nearly two acres of ground. The roof is formed of brick groined arches 21 feet high by 36 feet span, upon cast-iron pillars: an impermeable covering of coal-tar and lime is laid on a coating of rough plaster over the arches, and upon that is a layer of earth 8 inches thick, sown with grass. This immense room is lighted and ventilated by a series of skylights 13 feet 6 inches diameter; one at the centre of each arch. A vaulted cellar with brick pillars extends under the whole of the building, and contains the shafts for communicating the motion from a pair of engines of 100 horses' power, to the machinery in the mill; the flues and steam cases for warming and ventilating; the revolving fan for urging the air into the room, with the gas and water pipes, and the remainder of the space is appropriated for warehouses.

The heating and ventilating are effected by a large fan, which forces the air through the pipes of two steam chests, each 10 feet long, and containing together 364 pipes of 3½ inches bore: the temperature can be regulated by the quantity of steam which is admitted into the chests, or by allowing a portion of cold air to pass by without traversing the pipes; valves and doors in the flues permit any temperature which is desired to be obtained, or that degree of moisture which is essential for some part of the process of working flax. The general details of the construction of the building are given with the dimensions of the brick and stone work; the cast-iron pillars and caps, the wrought-iron tie-bars, with the reasons for adding a second set after the accident occurred to the first set; the mode of drainage from the roof; and the striking the centres of the arches, &c.

The total cost of the mill including the ornamental stone front was £27,443, which is stated to be about the same cost as that of a good fire-proof mill on the common plan; but as this mode of construction was novel to the workmen, it is probable that a second building of the kind would be less expensive. The advantages resulting from the plan are, convenience of supervision, facility of access to the machines, the power of sustaining uniformity of temperature and moisture, the absence of currents of air which are so objectionable in other mills, the simplicity of the driving gear, and the excellent ventilation which is so desirable for the health of the work-people.

The paper was illustrated by two drawings with a sheet of reference, and

an appendix contained the result of some experiments upon the strain on the tie-bolts, the pressure on the arches, and the deflexion of the bolts, &c.

Remarks.—Mr. Smith, of Deanston, was much pleased to find this description brought before the Institution, as he was the first to adopt it for a weaving shed of the extent of half an acre; the columns for carrying the arches were 30 feet six inches apart, and the skylights were 8 feet in diameter; some of the arches were of brick, with stone springers; others were entirely built with rubble stone well grouted, which latter mode of construction he found succeeded quite as well as brick: the settlement of the arches on striking the centres after standing four days was only ¼ths of an inch: The arches were thickly plastered with common mortar and at first were only covered with a coating of boiled coal-tar pitch, and lime ¼ths of an inch thick, but as the wet penetrated, the thickness of coal-tar pitch was increased to ½ths of an inch, with a mixture of sharp sand, which had proved perfectly water-tight: for some months there was an appearance of moisture, which proceeded from the interior of the brickwork, as it could not escape outwards on account of the impermeable covering; after some time the copious ventilation carried off this moisture and the building became perfectly dry. Over the coal-tar a thickness of earth is laid, which is cultivated, and has proved a prolific garden: in severe weather the frost has not reached above 1½ inch deep in the soil, while it has penetrated to the extent of 12 inches in other situations. The construction of the floor is peculiar: it is desirable in such weaving sheds to have a boarded floor, to prevent the small parts of the machinery from being broken by falls, and also on account of the health of the persons employed; but the vibration of an ordinary wood floor is objectionable. In order to meet these views, a bed of concrete was laid throughout the building, a series of small deal spars 1½ inch deep by one inch wide were set flush into the concrete whilst it was wet, and the whole surface was smooth plastered: upon this bed, when it was perfectly dry, a floor of boards 1½th inch thick was nailed to the spars: it was found to combine the solidity of pavement with all the advantages of a wood floor, and there had not been any symptoms of dry rot: which might be attributed to there being no cavities left beneath the boards, the whole being firmly bedded down. The ventilation was effected by tunnels beneath the floor, the covers of which were pierced with a number of small holes to spread the air. The warming was accomplished by means of hot water circulating under the pressure of the atmosphere only, in "tubes of tin plate" 4 inches diameter; the temperature was very regular and perfectly under control. With one ton of coal per week the shed could be kept up to 70° during the winter. The cost of this building was 30 shillings per square yard of area covered, which was less than the cost of Messrs. Marshall's mill, but building materials were much cheaper at Deanston than at Leeds. He expected that this mode of building would become more general as it combined many advantages, and whatever might be the first outlay in purchasing ground, the cost of which was the only inducement for constructing buildings of several stories in height, it would be fully compensated by the facility of superintendence alone, as in manufactories this was of the utmost importance. These buildings would, he believed, be eventually used for agricultural purposes, and when engineering knowledge was more directed to the processes of agriculture, good results might be anticipated: his attention had been particularly directed to the subject, and he was convinced of the necessity of concentrated superintendence which is not at present possible in the separate farm-steadings as they are now constructed: this might be apparently foreign to the subject before the meeting, but the range of engineering was so wide that it was difficult to say where it should stop.

Mr. Lindsay Carnegie as a landed proprietor could bear testimony to the importance of the connexion of engineering with agriculture, and to the advantages already derived from the improvements which had been introduced by Mr. Smith, who might be justly termed the father of the improved system of agriculture in Scotland.

Mr. Marshall explained that he was indebted to Mr. Smith for the suggestion of this mode of construction, which he had not hesitated to adopt although all the plans had been prepared for mills of several stories in height—he had been convinced of the superiority of the present plan and his expectations had been fully realized. There were of course some difficulties to be overcome and some experiments to try, all of which had not been successful, but in all the essential points this kind of building was superior to any other. An equality of temperature and a facility of imparting a certain degree of moisture to the air which was indispensable for spinning yarn had been perfectly attained.

Mr. Braithwaite inquired whether the arches were found to be perfectly water-tight? On some of the railways which were laid upon arches it had been found that asphalt had failed in rendering them impervious, and they were consequently useless, even for store-houses.

Mr. Marshall explained that a few leaks had occurred, particularly near the skylight-frames, but they had been easily repaired and were now water-tight.

Mr. Combe found that a mixture of finely-sifted engine ashes with the coal-tar pitch was better than lime. The depth of soil above the arches should be sufficient to prevent the heat of the sun from penetrating through the cracks to the pitch and forcing it up. He had recently examined the roof carefully and could only discover six indications of moisture penetrating; these had been easily repaired and all was now perfectly sound.

Mr. Field agreed with Mr. Smith in his estimation of the advantages of carrying on all manufacturing processes as much as possible under one roof and on one floor—great economy of time and labour would result, especially

where heavy masses such as parts of machinery required to be moved about—he would always adopt the system in constructing a manufactory.

Mr. Smith observed that an arched roof would be found as cheap as one of wood and slates, and in the relative durability there could be no comparison.

Mr. Marshall desired it to be borne in mind that the cut stone front of the mill had greatly enhanced the cost, and that being the first building of the kind erected in the neighbourhood of Leeds, it had naturally been more expensive than others would be.

"Account of the Explosion of a Steam Boiler at the Penydarran Iron Works, South Wales." By Adrian Stephens.

The boiler, the explosion of which is described in the paper, was one of a pair for furnishing steam to a high-pressure engine, with a cylinder of 26 inches diameter, working expansively, the steam being cut off at half the stroke; each of these boilers was 41 feet long, and 7 feet diameter, with a centre tube flue of 4 feet 2 inches diameter; the thickness of the plates throughout was $\frac{1}{2}$ inch; the ends were flat, with rings of angle-iron, and the pressure of the steam to which the safety valves were weighted was 50lb. on the square inch. From appearances after the explosion, it was conjectured that the tube, which was collapsed in a remarkable manner in its entire length, had been softened by the heat, having probably been left dry along the upper side. No opinion is given as to the cause of the explosion, but it is particularly mentioned that the supply of feed-water depended upon the regular attention of the engineer, and that the feed-pipe was placed so that the water fell directly upon the hottest part of the tube flue, and it is remarkable that the tube is most extensively fractured at that spot. All the appearances presented by the boiler both before and after the explosion and the injury done by the event are accurately detailed, and the paper was illustrated by a drawing of the boiler and the setting.

STONE BORING MACHINE.

Mr. Carnegie presented one of Hunter's Stone Boring Machines to the Institution, and explained its action to the meeting.

The machine is composed of two parallel bars of steel, supporting a traversing carriage, through the centre of which passes a spiral auger attached to a screwed bar; this bar fits into a female screw clamp above the carriage, and on the upper end is a winch with four handles. When the instrument is in use it is fixed by two cramps upon the stone to be pierced, and the auger being made to revolve by means of the winch, scoops out at each revolution as great a depth of stone as is equal to the distance which the screw descends; the chips ascending through the spiral channel of the auger, are thrown off at the top. The peculiar shape of the point of the auger prevents its being abraded, as it operates by chipping the stone, and not by grinding it away. This, with the means of forcing it down by the screw, is the chief novelty of the machine. It has been extensively used at

the works of the new Harbour of Arbroath, by Mr. Leslie, who speaks of it in the following terms:—

"Mr. Hunter's Boring Machine has been advantageously employed for above a year, in boring trenail holes in the stones used at the new Harbour of Arbroath. The holes are $1\frac{1}{2}$ inch diameter, and from 9 inches to 2 feet in depth: the aggregate of the holes already bored amounts to upwards of 30,000 linear feet. The machine may be adopted for boring holes of any dimensions. It does the work considerably cheaper than the "jumper," and much more correctly, as it makes the holes perfectly straight, cylindrical, and equal throughout, instead of the irregular form made by the common jumper. This machine is very well adapted for boring railway blocks, and has been much used in this quarter for that purpose. I consider it to be more especially valuable from the facility which it affords of boring and trenailing down the stones used in sea buildings in any exposed situation, as I have found that trenailing is a great security to such building while in progress, when the upper courses are much exposed and liable to be washed off unless they be held down by other means than their own absolute weight. The expense of boring the old red sandstone rock, here, is about three halfpence per linear foot.

Remarks.—Mr. Vignoles bore testimony to the advantages of the machine: he was now employing it for piercing holes in stones going from Arbroath to the West Indies for the construction of a patent ship—there was great economy of cost and time by its use in addition to the superior manner in which the holes were made.

Mr. Smith, of Deanston, was convinced of the advantage of the machine in working almost all kinds of stone, but more especially for those resembling the Arbroath stones, which were from a bed beneath the old red sandstone: they were of fine grit mingled with schistose debris. The action of the tool was like that of the stone-planing machine, to burst chips off instead of grinding down the surface by small portions and destroying the edge of the tool at the same time. With the planing machine it was common to take off a thickness of 3 inches at one passage of the tool—it acted like a "pick;" and being fixed in a frame weighing about $1\frac{1}{2}$ ton, the power was great; at the same time there was little abrasion of the tool and it never became heated or softened. It was probable that with other qualities of stone a screw with another pitch of thread might be required to force the auger forward, but with the thread now used in boring stones from the Arbroath quarries, the economy of time and cost appeared very great. In each of the blocks for the Arbroath railway it was requisite to bore two trenail holes $1\frac{1}{2}$ inch diameter and 6 inches deep—and to level a space 9 inches diameter to receive the cast-iron chair: this had been contracted for at twopence halfpenny per block, which was a material diminution of the usual cost. He was convinced that the instrument only required to be known to be extensively used.

Mr. F. Braithwaite had for some years used Hunter's stone-planing machines, for dressing up slate and other stones, and was well qualified to give a favourable opinion of the principle of its action: he believed that the machine under discussion being upon the same principle must be very useful.

May 24.—The President in the Chair.

"On the machinery used for working the Diving Bell at Kingstown Harbour, Dublin." By Peter Henderson, Assoc. Inst. C. E.

After referring for the details of the machinery to the two drawings which accompany the paper, the author describes the foundations of the pier head to have been laid in a depth of 20 feet at low water on rock and firm sand. For 14 feet from the bottom, the wall is formed of Runcorn sandstone of fine quality, each stone containing about 50 cubic feet and thoroughly squared. This has been preferred to granite on account of its cheapness and the facility with which it is worked under water. After the foundation course is secured, from 300 to 350 cubic feet of this walling are frequently set in a perfect manner by the diving-bell during a fair working day of eight hours. The first stone was set on the 5th of August, and by the 1st of January 16,000 cubic feet had been laid. From 6 feet below low water to the coping, it is proposed to make use of granite in blocks of 50 cubic feet each, which is procured cheaply and in abundance in the immediate neighbourhood. The piers are finished in the interior by walling of rubble stone carefully laid. For the purpose of forming this excellent harbour, an area of 251 acres has been inclosed between two substantial stone piers of 8,340 feet in length, affording clear anchorage in a depth of water from 15 to 27 feet at low spring tides. The interior shows no natural tendency to collect deposits likely to reduce the depth of water, nor do any of the works exhibit symptoms of deterioration, while its continual occupation by vessels of every description, together with the comparative freedom from accident in Dublin Bay, afford convincing proof of its great utility.

"Description of a Steam Dredging Engine used upon the Caledonian Canal." By Walter Elliot.

The machine described in this communication is not remarkable as being of the most perfect description, but as it is stated to be among the earliest which were brought into use in this country, a certain degree of interest is attached to it. It was constructed in the year 1814 expressly for the for-

mation of the Caledonian Canal, and it was also used for deepening the channels through the shoals in Loch Dochfour and Loch Ness. The length of the vessel is 80 feet by 23 feet in width; the bucket frame is 42 feet long, with 25 buckets, worked by a condensing steam engine of 6 H.P. The dimensions of all the principal parts of the machinery are given minutely, with accounts of several experiments for extending the use of the dredger. On one occasion, as it was found that the buckets had much difficulty in penetrating the hard mountain clay, every alternate bucket was removed and a pair of steel cutters substituted for each, in the expectation that the clay would be loosened and the succeeding bucket would take it up more easily. They did not, however, act satisfactorily, and a risk of fracture was incurred which induced the abandonment of the plan. On another occasion, in forming a portion of the canal between Loch Ness, and the lochs at Fort Augustus, where the height of the ground above the water averaged from 20 to 30 feet, and the excavation was required to be about 16 feet beneath it; that part of the cutting above the water level was commenced by manual labour, while the dredging machine did the excavation under water; it was soon found, however, that the engine having completed its share of the task, continued to undermine the upper portion, which, being of a loose nature, fell into the water, and was raised by the buckets so rapidly that the manual labour could not compete with the machine, and it was then used to complete the undertaking, which it did in eight months, having in that time excavated about 170,000 cubic yards of material. When working in favourable situations the quantity generally raised equals 90 tons per hour; 17 of the buckets are discharged per minute, with an expenditure of coal of about 15 cwt. per day. The communication was illustrated by two detailed drawings of the boat and its machinery.

"Description of the Maplin Sand Lighthouse at the mouth of the River Thames." By John Baldry Redman, Grad. Inst. C. E.

The paper commences with an enumeration of the various channels and sandbanks at the mouth of the Thames, with the floating lights, beacons, and buoys marking the entrances of the Channel, and gives the objections to floating lights, and the reasons for selecting the Maplin Sand as the position for a fixed lighthouse.

In the year 1837 a survey was made by Mr. Walker, the engineer to the Trinity House, and by boring it was ascertained that the first six feet of the sand was close and compact, but below that for 20 feet the boring rod went more easily as it descended, and it was found that it became mingled with argillaceous earth as the depth increased.

It was then decided to use for the foundations Mr. Mitchell's screw moorings, and in 1838 the patentee, under Mr. Walker's directions, commenced fixing nine cast-iron screws of 4 feet diameter so as to form an octagon with one screw in the centre; attached to each of these screws was a cast iron pile 5 inches in diameter and 26 feet long, which was inserted into the sand 21 feet below low-water mark. On account of the constant shifting of the sand from around the piles it was determined to place a raft or grating of timber around and between them; the surface of the raft was covered with faggots of brushwood well fastened to the timbers, and upon them was deposited 120 tons of rough Kentish ragstone, by which the raft was secured in its situation, and after a time no farther changes occurred in the level of the surface of the sand. In the summer of 1840 the superstructure was commenced; it consisted of nine hollow iron columns or pipes curved at the top to a radius of 21 feet towards the centre; they were secured upon the piles, and two series of continuous circular horizontal ties bound them together, while they were connected with the centre column by diagonal braces—all of wrought iron. Upon these columns is built a wooden dwelling for the light-keepers, in the upper part of which is placed a French dioptric light of the second order, its centre being 45 feet above the mean level of the sea, and at that elevation can be seen from a ship's deck at a distance of nine or ten miles; a bell is fixed on the gallery which is sounded by machinery at intervals during dark and foggy nights.

The communication gives all the details of the dimensions and the mode of fixing the cast iron screws and piles made by Messrs. Rennie's—the iron work by Messrs. Gordon's of Deptford—the wood work by Messrs. Gates and Horne of Poplar, and the lantern by Messrs. Wilkins—and the whole is illustrated by a series of drawings which fully describe this useful construction, which has hitherto withstood the most violent attacks of the sea to which it is exposed.

Remarks.—In answer to questions from the President, Mr. Wilkins stated that he had been in the Eddystone and the Maplin Sand lighthouses during severe gales of wind; that as might be conceived from the nature of the construction, the latter building was more affected than the former by the striking of heavy seas; the motion appeared to be more like torsion than simple vibration, which he attributed to the waves striking the ladder and its projecting stage, and thus tending to twist the upper part. Still the motion was not such as would cause injury to the building.

The President pointed out two diagonal braces extending downward from the end of the ladder stage to the piles on either side, which had been introduced in order to counteract the twisting described by Mr. Wilkins. In constructions of this nature it was of importance to oppose as little resistance as possible to the seas, especially in the upper part of the building, a system of bracing had therefore been adopted, which consisted principally of two series of continuous circular horizontal ties between the piles at the several heights

of 6 feet and 15 feet above low-water mark of spring tides. From the external ring of piles two sets of diagonal stays extended to the centre pillar, forming strong triangular trusses in the direction of each pile, and two sets of horizontal stays stretched between the piles and the centre pillar at the levels of the circular bands. The amount of direct vibration was very small, and he did not conceive that the twisting motion which had been described was sufficient to warrant the introduction of diagonal braces, which would materially augment the surface upon which the waves would act.

Mr. Vignoles directed the attention of the meeting to the system of diagonal bracing between the piles which had been adopted at the Port Fleetwood lighthouse; he apprehended that as the principal force of the waves would be exerted against that part of the structure which was above the high-water level, the diagonal braces extending between the upper part of the piles and the level of low-water were preferable to the horizontal continuous bands of the Maplin Sand lighthouse, although assisted by the system of radiating central truss braces which it possessed: he conceived that both buildings were strong enough for the purposes for which they were constructed, but he preferred the mode of bracing adopted in the Port Fleetwood house, the vibration of which he knew to be very small, although situated in an exposed position where the rise of the tide is 30 feet.

Mr. Donkin observed that there could not exist a doubt of the introduction of diagonal braces rendering the building stronger; how far they were necessary, or might be prejudicial in offering additional resistance to the passage of the waves, should be well examined before adopting them. He considered the position of the suspended ladder decidedly objectionable, as any torsion caused by the waves striking it must tend to dislocate the fibre of the material of the piles and to fracture them.

Mr. Farey believed the construction of the Maplin Sand house to be better adapted than the Fleetwood house for resisting the direct action of waves, but the diagonal bracing of the latter enabled it to withstand torsion better than the hoop bracing of the former. He inquired why the lower part of the light-keeper's house was made conical, as he apprehended that it would receive a heavier blow from a wave than if it had been flat.

The President replied that the main body of the waves seldom or never rose so high as the bottom of the house, and that the conical form allowed the air and spray to rise up and be guided off without affecting the building as it would do if the bottom was flat. With regard to the torsion, that had only been felt at first, when the ladder extended too low down and received a constant succession of blows from every wave, which naturally communicated a vibration to the whole structure; the ladder was now shortened, and nothing of the kind was felt: the waves scarcely, even in the roughest weather, struck the suspension stage or the boat. He preferred the continuous horizontal bracing, which bound all the piles firmly together like the staves of a barrel; and from observations he had made, he believed the amount of vibration to be greater in the Port Fleetwood lighthouse than in that at the Maplin Sand.

In answer to a question from Mr. G. H. Palmer, the President said that at present there was not any indication of a change in the condition of the cast iron from its contact with the salt water.

Professor Brande was unable to give any additional evidence on the observed facts connected with the change suffered by cast iron exposed to the action of salt water, or in mines and in various other positions—from experiments which he had made, he was led to believe that many of the appearances observed in the changes of cast iron arose rather from a peculiar mechanical combination of the molecules, than from a difference in the chemical constitution of the metal; no difference could be detected by analysis in the metal which had undergone change and that which had not. It should be remarked that the contact of two metals was not essential to cause galvanic action; a film of oxide upon the surface of the body of metal formed a very active galvanic pile: hence arose the necessity for preventing oxidation by proper paints or varnish before using pieces of cast iron in exposed situations.

Mr. Farey observed that in the early engines constructed by Woolf in Cornwall, in which the packing segments were of gun-metal and the body of the piston was of cast iron, wherever the two metals were in contact the iron was turned to plumbago; this had been particularly observed where high-pressure steam was used: it might be a question whether the temperature of the steam, and the quantity of mineral water carried over with the steam by the large amount of priming of the engines in that day, had not materially contributed to produce the effect.

Mr. P. Taylor believed that the temperature of the steam had not any connexion with the subject; in the metallic packing of steam pistons of low-pressure marine engines, which he had constantly under repair at Marseilles, wherever the wedge pieces were of gun metal, the backs of the cast iron segments were converted into plumbago, while those surfaces of cast iron which were ground together and worked against each other remained unchanged; the same might be said of the rubbing surfaces of cast iron against gun-metal; it appeared, therefore, that the formation of an oxide was necessary to commence the change. He repudiated the use of cast iron in situations where these changes were to be apprehended; he would employ wrought iron, as although that did become oxidized, it retained its relative strength to the last, whereas cast iron, when changed into plumbago, retained its bulk but lost nearly all power of cohesion.

Mr. John Taylor said that in Cornwall the cast iron pump-trees exposed to the action of mine water were very speedily destroyed; and even although 1½ inch thick, they could be cut to pieces with a knife when first taken out

of the pit. The air-pump buckets of steam engines, in which the body was of cast iron and the valves of gun-metal, formed the most perfect kind of galvanic apparatus; they should be made entirely of gun-metal. In manufacturing of vinegar and pyroligneous acid the decay of cast iron was very rapid.

Mr. Glynn attributed in a great degree the rapid decay of cast iron in coal mines to the presence of sulphuric acid evolved from the pyrites. Mr. Philip Taylor agreed with Mr. Glynn; even copper pipes were rapidly destroyed in the bilge water of vessels, which always contained much sulphuretted hydrogen—he recommended the use of stout lead pipes in such situations; they would be found much more durable.

Mr. Davidson had found it necessary to substitute gun-metal gratings for the cast iron ones at Messrs. Hanbury's brewery, as although they were $\frac{3}{4}$ in. thick, they had been entirely destroyed in four years.

The President gave a short account of the construction of a light-house now making by Messrs. Gordon & Co. at Deptford under his directions for the Point of Air. The lantern for it would be cast from a gun which had been raised from the wreck of the Royal George.

Sight-tube for Marine Boilers.

Mr. C. W. Williams exhibited and explained the sight-tubes which he now used for the marine boilers of the City of Dublin Steam Packet Company's vessels.

The instrument consists of a wrought iron welded tube 2 inches diameter with a screw thread cut upon the exterior; it is inserted across the water spaces of the boilers, and secured by means of nuts in such positions behind and opposite the furnace, as enables the engineer to see all that goes on interiorly, particularly the degree of perfection or imperfection in which the gaseous matter enters into combustion, and the effect of admitting or excluding the air.

The instrument had been found very useful, not only in experiments, but in practice on the large scale, and he deposited it in the Gallery of the Institution in order that it might serve as a model for those who were inclined to adopt it in marine boilers.

REPORT OF THE COMMISSIONERS ON THE FINE ARTS.

(Continued from page 308.)

VARIOUS COMMUNICATIONS ON FRESCO PAINTING.

The following papers contain further information respecting the practice of fresco-painting, or point out the sources where the subject is more fully treated. In inserting these communications and extracts, it has not been possible to avoid occasional repetition, but in some cases coincident testimony may be necessary to establish or recommend particular methods. While the question respecting the adoption of fresco remains, for the reasons before stated, undecided, it may appear premature to describe its methods so fully, but it is precisely because so little is generally known of the process, in this country, that it has been thought desirable to take this means of putting the artists and the public in possession of the information that has been collected.

A communication on fresco by Professor Hess, of Munich, (to Mr. William Thomas) need not be given at length, as it agrees generally with the foregoing statements by Director Cornelius. In speaking of the preparation of the wall Professor Hess recommends "bricks well dried, and of equal hardness" as the groundwork of the mortar and plaster. Mr. Thomas observes, "all the frescos in Munich are painted on the (plastered) brick wall: laths with wattling and copper nails are not approved of, as the risk of bulging is thus increased. The use of laths is sometimes necessary for certain surfaces, but the professors in Munich are decided that a brick ground is to be preferred wherever it is practicable, not only on account of its solidity, but also because it is better adapted for the execution of the painting. The brick ground absorbs superfluous water and keeps the plaster longer in a fit state for painting upon. The painting ground dries much quicker on laths as two surfaces are presented for evaporation. The walls ought to be thoroughly dry. A wall of a brick, or a brick and a half, in thickness, is preferable to paint upon. Professor Hess once observed to me that where the walls in the lower portions of buildings were five or six feet thick, the liability of saline

matter making its appearance was much increased, as the mass of wall remains longer in a humid state."

Mr. C. H. Wilson, professor of ornamental design in the Royal Edinburgh Institution, has contributed much useful information on the subject of fresco, derived from his own observation in Italy, and from recent communications from his father, Mr. Andrew Wilson, now at Genoa. He observes: "In Italy the practice of lathing walls is unknown, but many of the finest Italian ceiling frescos are on lath, and are in perfect condition. Most vaulted ceilings in what is termed the *piano nobile*, or principal floor of every palace, are constructed of wood. The lathing in this case is not attached to single thin pieces of timber, cut to the shape of the ceiling, but to a strong grating; in some cases the ribs and transverse pieces of this grating are four inches thick each way. The lathing in Italy is a very peculiar process. The material is the reed, which is cultivated so extensively in that country, and used in so many ways. It grows to the length of about 18 feet, and is rather more than one inch and a quarter diameter at the base. When these reeds are used for lathing they are split, and not being strong enough for the purpose in this state, they are wattled upon the grating. The result of this somewhat complicated contrivance is a framework of great strength."

Mr. Hamilton, a distinguished architect of Edinburgh, observes: "In the preparation of walls and ceilings for fresco-painting, no expense should be spared; battens and lath are obviously perishable materials, and therefore ought to be avoided. The damp from exterior stone walls may be guarded against by lining them with brick, and now that the use of cast-iron is so well understood, the girders or joisting of houses where fresco-painting is contemplated should be of iron arched with brick between, and thus a perfectly level ceiling may be formed of the most durable kind." For the more effectual prevention of damp, Mr. Hamilton recommends that the lining of brick should be somewhat detached, leaving a small space between it, and the stone wall, to which it could be bound at intervals. Mr. C. Wilson in communicating this opinion, remarks, that as the brick lining, added to walls of sufficient solidity for the support of the ceiling here described, would diminish the size of the rooms, tiles placed edgewise might be used instead of bricks. These should, however, be of sufficient strength to be in no danger of fracture from any ordinary accident. To guard against damp from roofs or even occasional washing of upper floors, it is also suggested that a coating of asphalt might be applied on the upper sides of the arches of the ceiling. In some cases asphalt might be necessary in walls: Mr. C. Wilson observes, that a French architect, M. Polonceau, effectually checked the progress of damp from a humid soil in several instances, by covering the horizontal surface of the masonry a few inches above the level of the soil with a coating of liquid asphalt, applied with a brush; when this was dry it was covered with a layer of coarse dry sand, and the building then proceeded. An external joint of hard asphalt at the same level is necessary effectually to cut off all communication of damp. (See the "Revue Générale de l'Architecture, September, 1841). These and other remarks on the construction of walls and ceilings have been communicated with all deference to the judgment and experience of the architect of the new buildings at Westminster.

In considering the question respecting the comparative fitness of laths and bricks, as a groundwork for fresco, it is not to be forgotten that the battened wall sooner adapts itself to the temperature of the atmosphere, and is therefore less likely to be affected by external damp; while the coldness of the more solid wall causes the rapid condensation of moisture in humid weather. This evil might perhaps be guarded against by due precautions with regard to temperature and ventilation.

Mr. C. Wilson next describes the mode of preparing the lime at Genoa:—"The lime having been slaked is mixed in a trough about six feet in length, and 20 inches in width; at the bottom it is somewhat narrower. The instrument used in mixing it is similar to that used by our masons. The lime is worked with this, and water is thrown in till the substance is of the consistence of cream. At the end of the trough there is a little sluice, the opening of which however comes only to within an inch and half of the bottom of the trough. On being drawn up, the sluice allows the lime to escape, but small stones or impurities which may have sunk to the bottom are prevented from passing by the ledge under the opening. The lime is received in a pit dug in the mere earth (not lined) to the depth of several feet, and of any convenient size. The process of mixing in the trough is repeated till the pit is well filled, the trough being washed out with clean water every third or fourth mixing."

"The lime being thus prepared is left in the pit from eight to twelve months* according to its ascertained strength. The lime for the first rough coat need not be kept more than two months: this is allowed to dry perfectly, before the next coats are put on. The proportion of sand to lime is the same as with us, viz. two of sand and one of lime. No hair is used by the Italian plasterers. The lime of which the *intonaco* or coat of fine plaster is composed, is however to be subjected to a much more careful preparation than that used for the first coat. After it has been kept the requisite time, it is taken out with a spade, the greatest care being necessary not to come too near the edges, sides, or bottom of the pit, lest any clay or earth should be taken up with the lime. It is now thrown again into the troughs, and is again thoroughly mixed with water, till it is not thicker than milk; it is then allowed to escape us before through the opened sluice, but this time it passes

* In Florence, where fresco-painting is now occasionally practised, a artist are of opinion that "the lime should be kept in the moist state from eight to twelve months, otherwise it will burn both colours and brushes."

through a fine hair sieve into an earthenware jar; a number of these jars are required, and each is filled to within a third of the top. The lime is allowed to settle, and when the water which rises over its surface is clear, it is poured off. This is repeated till there is no more water to pour off, and the lime remains in the jar of the consistence of the white paint commonly used, and is quite as smooth. It is now ready to be mixed for the *intonaco*, which consists as usual of two parts sand and one of lime. Great pains are taken in Italy to find a suitable sand: it must be perfectly clean, sharp sand, the grains of equal size, and its colour favourable, as the *intonaco* should not be too dark. The presence of any earthy particles in the plaster would inevitably ruin the fresco: this accounts for the very careful preparation which all the materials used undergo."

Professor Hess recommends avoiding the intermixture of plaster of Paris in the mortar for the first rough coat (in the finer coats it is never employed as a preparation for fresco) and advises a moderate use of small flint pebbles. The rough coat should not be too compactly laid on, as its porosity is essential to the convenience of fresco painting. In like manner the last finer coats should be lightly floated on to ensure their power of absorption. He proceeds: "The plaster for painting on is composed of lime not in too caustic a state and pure quartz sand. With regard to the lime it should be well and uniformly manipulated, and should be entirely free from any small hard lumps. The sand should be very carefully washed to cleanse it from clayey or saline particles, and should be afterwards dried in the open air. Sand that is coarse or unequal in grain should be sifted; thus the plaster will be uniform in its texture. The proportion of sand to the lime is best learned from experience, and must depend on the nature of the lime. If the plaster contains too much lime it becomes incrustated too soon, is too smooth in surface and easily cracks; if it contains too little it is not easily floated, the successive patches (as the fresco proceeds) are not to be spread conveniently in difficult situations, and the plaster is not so lasting.

"Before laying on the plaster, the dry rough coat is wetted with a large brush again and again, till it will absorb no more. Particular circumstances, such as spongy bricks in the wall, humid or very dry weather &c. dictate the modes in which this operation is to be regulated. The plaster should be laid on lightly and freely with a wooden hand-float; in connecting the successive patches some portions require however to be finished with an iron trowel; in this case care must be taken not to press too strongly, otherwise rust spots might appear in the lime, and even cause portions of the superadded painting to become detached. [A glass float seems to be preferable where a wooden instrument is unfit.] The plaster should be about a quarter of an inch in thickness. The surface of the last coat is then slightly roughened to render it fitter for painting on. The wall thus prepared is to be left a quarter or half an hour before beginning to paint."

The colours enumerated by Professor Hess are the following. "White: lime which has either been long kept, or by repeated manipulations and drying is rendered less caustic. Yellow: all kinds of ochres, terra di Sienna, Red, all kinds of burnt ochres, burnt terra di Sienna, [the brightest particles selected at different stages of the process of burning, furnish, according to Director Cornelius, very brilliant reds,] oxides of iron, and lake-coloured burnt vitriol. Brown: umber, raw and burnt, and burnt terra vert. Black: burnt Cologne earth, which when thus freed from its vegetable ingredients, affords a pure black. Purple: burnt vitriol, cobalt blue, and lake-coloured burnt vitriol. Green: Verona green (terra vert), cobalt green, and chrome green. Blue: ultramarine, cobalt, and the imitation of ultra-marine; the last is most safely used for flat tints, but does not always mix well with other colours. These colours have been well tested, and for the most part admit of being mixed in any way. Other more brilliant colours, such as chrome yellow, vermilion, &c., have been tried in various ways, but have not yet in every case, been found to stand. Colours prepared from animal and vegetable substances cannot be used at all as the lime destroys them." Fresco-painters observe that "great attention is necessary in the due preparation of tints on the palette, for if tints are mixed as the work proceeds, the painting when dry will appear streaky: when the colours are wet the differences are not so perceptible."

In additions to hog's hair tools, which, as before observed, are longer than those used in oil painting, "small pencils of otter hair in quills are used. No other hair resists the lime, but becomes either burnt or curled. The palette of the material and form before described, is covered with a light coloured varnish to protect the tin from rust. Rain water (that has not passed through an iron tube,) boiled or distilled water should be used from first to last in all the operations of fresco-painting."

Professor Hess continues:—"After the painter has laid in his general colour, he should wait half an hour or an hour, accordingly as the colour sets, before he proceeds to more delicate modelling. In these first operations he should avoid warm or powerful tints, as these can be added with better effect as the work advances. After the second painting and another shorter pause, the work is finished with thin glazings and washings. In this mode the requisite degree of completion can be attained, provided the daylight and the absorbing power of the plaster last. But if the touches of the pencil remain wet on the surface, and are no longer sucked in instantaneously, the painter must cease to work, for henceforth the colour no longer unites with the plaster, but when dry will exhibit chalky spots. As this moment of time approaches, the absorbing power increases, the wet brush is sucked dry by mere contact with the wall, and the operation of painting becomes more difficult. It is therefore advisable to cease as soon as these indications appear.

"If the wall begins to show these symptoms too soon, for example in the second painting, some time may be gained by moistening the surface with a large brush, and trying to remove the crust or setting that has already begun to take place: but this remedy affords but a short respite. In the additions to the painting on successive days, it is desirable to add the new plaster to that part of the work which is not quite dry, for if added to dry portions the edges sometimes exhibit spots. Various other effects sometimes take place from causes that cannot be foreseen, and the remedies must be provided by the ingenuity of the artist, as the case may require."

The following extract from a letter addressed by Mr. Andrew Wilson to his son (in March last) will render the process of painting in fresco more intelligible; but it is almost needless to observe, that in such details, the practice of painters may vary considerably.

"I lately went to the royal palace (Genoa) to see the Signor Pasciano paint a ceiling in fresco. His tints had all been prepared before my arrival: he had only two in pots, viz. pure lime and a very pale flesh tint. He had no palette, but a table with a large slate for the top: on it he set round, 1. Terra vert. 2. Smalt. 3. Vermilion. 4. Yellow ochre. 5. Roman ochre. 6. Darker ochre. 7. Venetian red. 8. UMBER. 9. Burnt umber. 10. Black. These colours were all pure, mixed only with water and rather stiff put down with a palette knife, perhaps about an ounce, or two at most, of each. He mixed each tint as he wanted it, adding to each from the pot of flesh tint or that of white. Near him lay a lump of umber, and on taking up a brushful of colour he touched this with it; the earth instantly absorbed the water, and he was thus enabled to judge of the appearance which the tint would present when dry. The painter used a resting stick with cotton on the top to prevent injury to the *intonaco*. The *intonaco* being prepared in the manner which I have described, the moment it would bear touching, he set to work. The head was that of the Virgin; he began with a pale tint of yellow round the head for the glory, (the colour of the ground, owing to the mixture of sand with the lime, it is to be remembered is a cool middle tint,) he then laid in the head and neck with a pale flesh colour, and the masses of drapery round the head and shoulders with a middle tint, and with brown and black in the shadows. He next, with terra vert and white, threw in the cool tints of the face; then with a pale tint of umber and white modelled in the features, covered with the same tint where the hair was to be seen, and with it also indicated the folds of the white veil. All this time he used the colours as thin as we do in water colours; he touched the *intonaco* with great tenderness, and allowed ten minutes to elapse before touching the same spot a second time. He now brought his coloured study, which stood on an easel, near him, and began to model the features, and to throw in the shades with greater accuracy. He put colour in the cheeks and put in the mouth slightly, then shaded the hair and drapery, deepening always with the same colours, which become darker and darker every time they are applied, as would be the case on paper for instance. Having worked for half an hour, he made a halt for ten minutes, during which time he occupied himself in mixing darker tints, and then began finishing, loading the lights and using the colours much stiffer, and putting down his touches with precision and firmness: he softened with a brush with a little water in it. Another rest of ten minutes: but by this time he had nearly finished the head and shoulders of his figure, which being uniformly wet, looked exactly like a picture in oil, and the colours seemed blended with equal facility. Referring again to his oil study, he put in some few light touches in the hair, again heightened generally in the lights, touched too into the darks, threw a little white into the yellow round the head, and this portion of his composition was finished, all in about an hour and a half. This was rapid work, but you will observe that the artist rested *four times* so as to allow the wet to be sufficiently absorbed into the wall to allow him to re-pass over his work.

"The artist now required an addition to the *intonaco*; the tracing was again lifted up to the ceiling, and the space to be covered being marked by the painter, the process was repeated, and the body and arms of the Madonna were finished before I left him at one o'clock."

The following is an extract from a second letter. "Yesterday I went again to see Pasciano, and I found that he had cut away from his tracing or cartoon those parts which he had finished upon the ceiling: in fact I now found it cut into several portions, but always carefully divided by the outline of figures, clouds or other objects. These pieces were in some instances a good deal detached from each other, and were nailed to the plaster so as to fold inwards or outwards for pouncing the outlines. The *intonaco* had just been fresh laid for the upper half of an angel supporting the feet of the Madonna: this was one of a group much larger than those surrounding the glory, and therefore requiring more colour and finish; more than half of the figure too was in shadow, with a strong ray of light on the face and on one of the arms: this was a good opportunity of observing the painter's management of shadow. Having gone over the outline carefully with a steel point, he waited till the *intonaco* became a little harder, and in the mean time mixed up a few tints, he then commenced with a large brush and went over the whole of the flesh: he next worked with a tint which served for the general mass of shadow, for the hair, and a slight marking out of the features. He now put a little colour into the cheeks, mouth, nose and hands, and all this time he touched as lightly as he possibly could, not to wash up the *intonaco*. He then halted for ten minutes, looking at his oil study, and watching the absorption of the moisture, and he called my attention to his outline: none of it was effaced by this washing.

"The *intonaco* would now bear the gentle pressure of his fingers, and

with the same large brush, but with water only, he began to soften and unite the colours already laid on. Observe, he had not as yet used any tint thicker than a wash of water colour, and he continued to darken in the shadows without increasing the force or depth of colour. This I before noted to you, that you can strengthen by the simple repetition of tint, but if the day be very dry, after an hour or two this process of repeating with the same tint produces an opposite effect, and instead of drying darker, it actually dries lighter. [See this explanation in the communication by Professor Hess.] I now observed that the painter had increased the number of his tints, and that they were of a much thicker consistence, and he now began to paint in the lights with a greater body of colour, softening them into the shades with a dry brush, or with one a little wet as he required. In drying, the water comes to the surface, and actually falls off in drops, but this does no harm whatever to the work although it sometimes looks alarming."

Mr. C. Wilson observes that the Aurora of Guido in the Rospigliosi palace in Rome was painted on a copper trellis, and afterwards fixed on the ceiling where it still exists. He adds that this fresco was offered for sale about fifteen years since, and that its safe removal was guaranteed. Mr. W. Thomas states that some small (landscape) frescos by Professor Rottman, in the Hofgarten in Munich, were painted on an iron frame and wire-work, and fixed in their situation afterwards. The example of Guido's Aurora, the figures of which are larger than life, shows that it would be possible to prepare movable frescos for situations where this might be thought necessary; for example, before flues or tubes in walls. But it is to be remarked that flues behind frescos have generally injured them. Mr. Aglio, who painted some frescos at Manchester some years since, attributes the great alteration of the colours in them partly to this circumstance; but also to his having been supplied with lime that was much too fresh. Cavaliere Agricola, in examining the frescos of the Vatican, found that the "Heliodorus" had suffered considerably from a flue behind it. The plaster had been detached from the wall, and projected in some places nearly four inches: it had been secured with nails, and the cracks had been filled with some composition by Carlo Marotti in 1702. The fresco of the "Defeat of the Saracens at Ostia" has been injured in like manner by a chimney behind it.

Detaching frescos from the wall.—In connexion with the subject of movable frescos it may be observed that the operation of detaching the mere painting from the wall, almost independently of the plaster, has been often practised with success. Although less immediately connected with the present inquiry, it is desirable to make this process known, as, in repairing churches and other buildings in England, many ancient paintings on plaster have been destroyed, from ignorance as to the means of removing them. Mr. Ludwig Gruner gives the following account of the mode in which he detached some frescos at Brescia in 1829. The convent of St. Eufemia in that city was then undergoing repair, and the excellent frescos it contained, painted by Lattanzio Gambara in the 16th century, would have been destroyed, when Mr. Gruner succeeded, with the assistance of some expert Italians, in removing them from the walls. The mode they adopted was first to clean the wall perfectly: then to pass a strong glue over the surface, and by this means to fasten a sheet of fine calico on it. The calico, after having been rivited to the irregularities of the wall, was afterwards covered with glue in like manner, and on it was fastened common strong linen. In this state heat was applied, which caused the glue even on the fresco to sweat through the clothes, and to incorporate the whole. After this a third layer of strong cloth was applied on a new coat of glue. The whole remained in this state two or three days, (the time required may vary according to the heat of the weather). The superfluous cloth extending beyond the painting was now cut off so as to leave a sharp edge: the operation of stripping or rolling off the cloth began at the corners above and below, till at last the mere weight of the cloth and what adhered to it assisted to detach the whole, and the wall behind appeared white, while every particle of colour remained attached to the cloth. This operation shows that the colours in fresco do not penetrate very deeply: the layer of pigment and lime which was detached in this instance was extremely thin, the outlines and even the colours of masses were visible at the back of the cloth. It is the opinion of some of the Munich professors that frescos thinly painted are least liable to change; the example just given, exemplifying as it does the practice of a skilful Italian fresco painter, seems to confirm this, but in many instances the surface of frescos even by the older masters is solidly painted. To transfer the painting again to cloth, in completing the operation above described, a stronger glue is used which resists moisture, it being necessary to detach the cloths first used, by tepid water, after the back of the painting is fastened to its new bed.

The frescos by Paul Veronese, in the Morosini Villa, near Castel Franco, were removed by Count Balbi of Venice, a few years since: he fastened cloth to the wall with a paste composed of beer and flour, and rivetted it to the irregularities of the surface by means of a hammer composed of bristles. Several of these works when re-transferred to canvass were sold in England in 1838. The operation of removing frescos has been lately performed with success in Florence and elsewhere.*

Vol. 18, num. 52.—Girolamo Baruffaldi, *Vita di Antonio Contri, pittore e rilevatore di pitture dal muro. Venezia*, 1834.—Cenni sopra diverse pitture staccate dal muro e trasportate su tela, &c. Bologna, 1840.

LAST DAY OF WILKIE'S EXHIBITION AT THE BRITISH GALLERY.

SIR—Do you admit gossip as a relief to Science? if so, the following reminiscences may amuse your readers.

B. R. H.

An exhibition of the best works of a great artist after he is dead, at our British Gallery, is the last tolling of his funeral bell;—the last effort of those who respected his character, and wish to put the seal upon his fame—before leaving both to the unbiassed and sifting decision of a future generation. How must the artist and the public have been indebted to the British Gallery!—how much the public taste has been solidly advanced by its various exhibitions of fine works!—what good has been done—what knowledge has been indirectly inculcated; how greatly the standard of excellence in the country has been raised, since these May displays began: what a study it is to look forward to;—now we have the majestic cartoons, then the crimson splendour, and golden tones of Titian; now the pearly glitter of Veronese, then the startling dash of Tintoretto: at one time the gorgeous glory of Rubens, and mysterious depth of Rembrandt, at another the sunny loveliness of Claude, and savage poetry of Salvator; sometimes we are enchanted by Corregio, or instructed by Poussin; and then came the modern school; Reynolds who might fear comparison with none for grace, for character, for taste, for touch, for gemmy surface, in portrait, for the quivering sweetness of children, and who was equal to all and often superior to all, in the splendid depth and keeping of a back ground.

Gainsborough, with his sketchy richness, followed Hogarth with his blunt touch and bitter satire, and this year we have had David Wilkie, with his sound sense, his perspicuous conception, his beautiful composition, his natural expression, and his unaffected drawing; the founder of our domestic school.

In musing on the whole of Wilkie's works, from the earliest to the latest, there is the same sterling sagacity, and sense; the story, the expression, the composition, never vary in intelligence or power.

His incessant changes of practice, had something approaching to a feeble hallucination of intellectual power; why a man so consistent, and persevering, so unalterable and honest in one mode of conduct, morally which founded his domestic fortune, should be so vacillating and uncertain, so childish and changing, so furious in the morning at the discovery of the previous evening, and so disgusted the next day at what he thought such a philosopher's stone the day before, is not to be accounted for, but from some inherent imbecility.

The gem of this collection, without prejudice to others, is the card players, and here his practice was perfect—this is a work, in point of vigour, depth, daylight, tone, strength, touch, expression, finish, completeness, and life, no picture of the Dutch school, by Teniers, ever surpassed it in execution, whilst in point of story and sense, no picture by Teniers ever approached it.

I can tell the artist why this work is so extraordinary in power.

1st, It is the only picture he *prepared* for ultimate glazing.

Glazing softens and flattens, and if a picture to be glazed be not painted sharper in touch than nature, it will be flatter than nature when glazed.

2nd. He never lost sight of his ground in his deepest shadows, and finished his darks under the table and elsewhere by repeated thin glazings over each other—the ground always showing through.

Thus, in very early life, he hit on the system of Teniers, he hit on the principle of the Venetian, Flemish and Dutch schools, though scumbling is more applicable to the two latter, as an ultimate resource, and nothing could be so self-evident as the superiority of the picture or vigour, in spite of his greatest work, (the Duke's Chelsea Pensioners) and his Murray Group in Knox, one of the finest groups for everything in art the world can show.

In his early work, he ruined all color, by a heavy intermixture of a heavy and hot yellow tint in every portion of his work—with the single exception of a little picture he painted in Edinburgh, belonging to Dr. Darling, of the Village Politicians; at the repeated entreaty of the late Sir George Beaumont, of Jackson and myself, he tried flesh without it, and the right hand of the Blind-fiddler was his first attempt; yet it must be acknowledged he had no eye for colour, if he had had, he would have known when he had produced a fine tint, which he certainly did not, for after producing a fine tone, you are as likely to find it ruined the next day; not like Sir Joshua, because he was longing for something richer, but because Wilkie's eye was never satisfied till he got some other tone, *not so rich*.

The nonsense which has been written about him this season, is

melancholy; one man says he had *no imagination*, because he painted his bottles and pans from nature!—another, he had no genius, because he took so much trouble and made so many drawings of one thing, hand or foot!—a third, that he painted circumstance and not character!—what has imagination to do with a brass pan?—what is wanted in a brass pan or a bottle, is, the reality of a brass pan and a bottle; now, that painting those things from the realities, instead of trusting to his memory, argues no imagination, is rather refined. Again, as to his taking trouble, who took more trouble than Raphael? had *he* no genius because he took trouble to be perfect in comprehending the objects to convey his thoughts? "Draw the naked figure first," said a connoisseur to a young artist, "as Raphael did." "Oh," said the young man, "that would be *losing time*;" no, my young friend, it would be gaining time and not losing, and when fresco begins you will find it out.

The Breakfast is another of his best works, and perhaps The Servant Girl pouring out the Water, is more like a woman, than any other he ever painted of that beautiful sex.

Thus then for ever ends the exhibition of a collection of this extraordinary man's works; his genius first startled the school from its slavish imitation of Reynolds; and though a great æra is commencing, that æra I have always foretold and laboured hard to produce, I can imagine no period of excellence that may hereafter arise, wherein the works of David Wilkie may not be studied, with benefit and instruction, either for fresco or oil.

Poor Sir David!—how many days we have passed in early life!—after painting all day, we met at dinner, and hurried to the Academy from 6 to 8—then went home to each other's rooms to criticize and advise on our mutual labours, animating each other with fresh hopes, and parted for the night with ardent aspirations for fame and distinction. Lord Mulgrave was our employer and kind friend, at his table we used to meet the first men of the time; Lord Mulgrave was a noble character, and had great delight in the society of artists and connoisseurs—after the fatigues of office, nothing pleased him so much. What reminiscences I could write—what a guide book for students would our mutual lives be, our mutual hopes, our mutual anxieties, our mutual fears, our mutual victories, our mutual defeats. A frequent guest was George Colman, whose wit and fun were perpetual sources of sparkle; Lord Mulgrave's brother had attempted to discover the North Pole; a series of pictures relating to the attempt hung round the dining parlour; before leaving the room, long discussions used to take place on art, the whole party walking round; in Captain Phipp's hand was a boat-hook; Sir George Beaumont once said "What has he got in his hand?" "Why," said Colman in his burly joking voice, "*I take it to be the North Pole!*"—At another time, after dinner everybody at table seemed sullen and indigestible—we had been painting all day, and were exhausted—Lord Mulgrave was exhausted and said nothing—and there was silence so long, that all of a sudden the whole circle made a sort of spasmodic effort to say something; Sir George in a lazy sort of a way observed "Theodore Hook is a delightful fellow." "Is he," said Lord Mulgrave, with a look at us all, "*I wish to God he was here now*;" this put everybody laughing, and the whole evening was delightful.

The going to the Academy every night, we always considered a necessary winding up of a day's study, but the theatres Covent Garden and Drury Lane were sources of dispute—when Mrs. Siddons acted I used to appeal to Wilkie, and when it was Mother Goose he used to dwell on the bill, and insist on it, he wanted to *study the expressions in the pit*!—sometimes he saved me from temptation, and sometimes I saved him! Once in going home through the Piazzas there was a show, a man in a thundering voice was explaining its wonders; as if by instinct we squeezed in, and getting up in a dark corner, hoped not to be seen; at last in dropped one after the other 16 students—long before they were all in recognition took place, so that a hearty shout welcomed every new face to its utter dismay; many of them are now living, the most distinguished artists of the day; the show was the Baker and the Devil, and it is impossible for people who are never worn out by 10 or 12 hours' painting, to comprehend the relish of students for such absurdities.

To travel with Wilkie was entertaining; in 1814, we went to Paris, and saw the town in its glory; we were joined by a Lincolnshire gentleman, who added much to our pleasure, and the only time I ever saw Sir David yield to a true "abandon," was coming out of Rouen; champagne had got to his heart, and opened its natural sources; we were in an open carriage, and I proposed we should sing "God save the King," as we left the city. Wilkie joined most heartily, and on passing into the road, an elegant Frenchman and two graceful women stopped to look at us with pleasure and astonishment!—as we concluded the last line, he turned from us smiling, and said "*Ah! trois milords.*"

But enough—when a dear old friend goes first in the maturity of life, one is apt to dwell too long on days which are passed for ever.

B. R. HAYDON.

PROTECTING CHURCHES FROM THE EFFECTS OF LIGHTNING.

[The following communication appeared in the *Times*, we believe it to be from the pen of Mr. Hood, whose scientific attainments entitle the paper to the especial notice of architects.]

Many persons are of opinion that fatal effects from thunder storms are more frequent now than they were formerly. I should myself be of that opinion if I trusted merely to the records of memory, but I find that, for more than half a century, the same opinion has been held; while at the same time observations made at different periods certainly negative this conclusion. Although it would be attended with much labour to collate all the accounts of accidents of this description, we may gather from the tone of the writers of former days what was the general impression on this subject. The *Philosophical Transactions of the Royal Society*, as well as many of the scientific periodicals published at the close of the last and the beginning of the present century, contain numerous interesting accounts of the effects of lightning; and a writer in the year 1811 states that he has made calculations of the average amount of damage by lightning in England, which he finds amounts to about £50,000 in money, and from 20 to 30 human lives, as the annual sacrifice by this destructive agent.

But it is extraordinary that, notwithstanding this acknowledged loss and destruction, scarcely anything is done to mitigate its effects. Science is certainly able to mitigate these destructive effects, if it were put in requisition for this purpose. The vast number of churches which have been damaged by lightning within the last three or four years—of which the last instance is St. Martin's Church, the damage to which is estimated at £3,000—suggests the necessity for adopting some mode of protecting this description of buildings, for it is certainly most extraordinary that buildings which from their height and general form are more liable than any others to suffer from lightning should so very seldom have any means of protection. With the exception of St. Paul's Cathedral, I believe very few churches in England, either in the metropolis or elsewhere, are furnished with lightning conductors, while many, or indeed most of them, are so constructed as almost to invite the electric fluid without the means of afterwards allowing its escape, except by the destruction of some part of the building. It is singular how nearly identical are the records of all the accidents of this kind which have hitherto occurred. In 1674 St. Bride's Church, Fleet-street, was struck with lightning; the electric fluid entered at the top of the spire by the gilded vane, from which it descended as far as any metallic conductors extended, and then burst through the resisting medium of the stonework, shattering the steeple and throwing down several stones, one of which, weighing 70lb, was carried a distance of 50 yards, and fell through the roof of a neighbouring house. With slight variations this would describe most of the accidents to churches from lightning; the force of the discharge of course depending upon circumstances. Nearly all writers on this subject are agreed, that if churches and other similar lofty buildings were provided with proper conductors, not only would they be protected from the lightning, but they would, in most cases, also defend the neighbourhood from its effects, by silently and imperceptibly drawing off the electricity from the clouds, and thus preventing the violence of the thunderstorm. In fact, this mode of preventing thunderstorms has been often proposed for adoption on a large scale: and it is somewhere narrated (though I cannot now recollect the precise authority) that a village in France, which from some local cause had been repeatedly devastated during a series of years by storms of lightning and hail, was afterwards completely protected by the erection of a number of elevated conductors. It is true that it has never yet been clearly ascertained the greatest extent of surface which a lightning conductor will protect, and, therefore, the precise degree of protection to the neighbourhood may be questioned, except within a certain limited distance—the protecting power of a conductor having been ascertained to be at least sufficient for an area represented by a circle whose radius is twice the length of the conductor.

The best practical instructions for the erection of lightning conductors is the report made to the French Government by M. Gay-Lussac, on behalf of the Academy of Sciences at Paris, published in the *Annales de Chimie*, and also in the 24th volume of the *Annals of Philosophy* for 1824; but, as these volumes are not often in the hands of practical men, it would be most desirable if the Royal Society would pub-

lish, in some form applicable to the intended purpose, instructions on this subject, combining the improvements which science has suggested since the period of M. Gay-Lussac's report. It is by no means improbable that many parishes might be induced to erect conductors on their churches, but the subject is so little understood that no one ventures to propose it; and unless these conductors are properly erected they are more likely to do harm than good.

The old cathedral of St. Paul's was twice struck with lightning, and both times seriously damaged. In 1444 the lightning destroyed the tower of the church, and in 1561 it set the church on fire and nearly burned it to the ground. In 1769 the Dean and Chapter applied to the Royal Society for their advice as to the best means of securing the present cathedral from the effects of lightning, and a short description of the mode adopted in this immense edifice may be interesting.

The ball and cross are supported by seven iron rods; these rods are then connected with other rods (used merely as conductors) which unite them with several large bars descending obliquely to the stone work of the lantern. A ring made of iron, one inch square, connects all these bars, and four iron bars, one inch square, connect this ring with the lead covering of the great cupola, a distance of 48 feet; and from thence the communication is continued by means of the pipes which discharge the water on to the floor of the stone gallery. From these pipes large strips of lead connect them with the pipes which discharge the water on to the roof of the building. This roof is entirely covered with lead, and from thence the communication is continued to the ground by means of the lead water pipes, which pass into the earth, thus completing the entire communication from the cross to the ground, partly through iron, and partly through lead. On the clock tower a bar of iron, one inch and a quarter square, connects the pine apple at the top with the iron staircase, and from thence with the lead on the roof of the church. The other tower has a bar of iron of the same size extending 88 feet from the pine apple to the roof of the church. By these means the metal used in the building is rendered available for the purpose of the conductors, the metal employed merely for the conductors being exceedingly small in quantity.

The general neglect of the use of lightning conductors probably arises from the belief of their insufficiency and ignorance of their proper construction. But it can be satisfactorily shown that wherever they have failed to afford protection it has arisen from either defective construction or subsequent derangement.

Earl-street, Sept. 6.

H. C.

GREAT BRITAIN STEAM SHIP (LATE MAMMOTH).

The *Mechanic's Magazine*, No. 996, gives an account of the construction and dimensions of this ship, together with drawings of her machinery and its arrangement, explanatory, although necessarily drawn to a very small scale; and useful, could we depend upon their accuracy; but the author (Mr. Hill) tells us "his rough dimensions were obtained by pacing, others by a graduated walking stick," a system of mensuration somewhat unusual among engineers of the present day. From the materials there furnished we form the following calculations:—

The diameter of each cylinder is said to be 88 inches, the stroke 6 feet, which at 19 strokes per minute, or 228 feet, is equal to 295 horses each, or of four cylinders to 1180 horses, and not of 1000, as stated by the author. Thus, area $\frac{88 \times 7 \times 228}{33,000} = 294.15$ horses or

1176.60 for four engines, doubtless intended to be of the collective power of 1200 horses, which in fact an additional $\frac{1}{4}$ of a stroke per minute would produce. The air pumps at 3' 9" diameter and 6' 0" stroke have a content of 66.24 cubic feet; one pump and condenser being apportioned to two cylinders. The cylinders have a content of 253.38 cubic feet; both = 506.76 cubic feet, we have therefore $\frac{506.76}{66.24} = 7.7$

times, or about the proportions of our best engineers. The condensers are $12.0 \times 8.6 \times 5.0$. content = 510 cubic feet, here we have $\frac{510}{66.24} =$

7.65 times, or nearly thrice as much as experience shows to be necessary. If any dependence is to be placed on the boiler sketches, the Bristolians have yet much to learn in that department of marine engineering. We are inclined to doubt their authenticity, for having so good an example as the boilers of the Great Western before them they ought to have certainly produced something nearer perfection, but of course we can only reason on what is before us. For example, we have 24 fires, each 6 feet long by 2 feet wide, a total grate surface of 288 feet for 1200 horse power, or about $\frac{1}{4}$ of a foot per horse power (nominal)

or less than half the proper quantity. This fact, coupled with the different arrangement of the flues, are plain indications that the consumption of coals will be the reverse of economical.

We make this analysis with reference to an article on "The Great Britain, the largest vessel in the world," published in the *Times* last month, wherein it is stated she has stowage for 1000 tons of coals and 1200 tons of measurement goods. The former amount seems inadequate for the purpose intended, viz., a voyage from Bristol or Liverpool to New York.

If we take the consumption at the moderate computation of 8 lb. per H.P. nominal per hour, we have $1200 \times 8 = 9600$, or per day = 103 tons; and supposing an average passage 12 days, the consumption would in that time be 1236 tons of coals without any surplus for the contingency of bad weather and prolongation of voyage. We think the consumption of coals will be nearer 10 than 8 lb. per horse per hour; and if we are correct in this opinion, we have 1200 lb. per hour, or, 129 tons per day, or 1548 for a voyage of 12 days—and mind, no surplus.

But, will she make the passage in less than 12 days? The same authority informs us that her load line is at 16 feet; at this, her immersed section is about 600 feet. Taking the powers as the cubes of the velocities, and using the factor 1400 (which experience shews to be correct for this class of vessel) we have $\frac{1400 \times 1200 \text{ H.P.}}{600 \text{ section}} = 2800 =$

14 miles per hour in still water, presuming her to be propelled by paddle wheels; but according to the Great Western experiments, as stated in *Mech. Mag.* p. 255, the screw is inferior to the wheel in the proportion of 12 to 10, or one fifth, so that instead of 14 miles her true velocity will probably be 11.65 miles, in still water, as aforesaid.

Now, Cunard's packets attained a greater velocity than 11.65 miles when tried experimentally, and yet their average passages, show a sea speed of about 8 $\frac{1}{2}$ miles only, the average length of passage being 13 days 16 hours out, and 11 days 5 hours home. The passage out gives 7.86 miles per hour, while that home influenced by prevailing wind and current gives 9.3 miles, in this case the mean sea rate is 8.58 miles per hour.

We take these facts from the *Nautical Magazine*, subsequently published in the *Times*, it appears to be a compilation from registered results, and therefore entitled to the highest credit. It states the passages of Cunard's line to be outwards, from 10 days 19 hours to 16 days 12 hours, and one reached 20 days 17 hours; the home passage from 9 days 17 hours to 12 days 18 hours, and this between Liverpool and Halifax only.

We draw two conclusions from these data: the first, there is no reason to suppose the Great Britain will make quicker passages than the present vessels; the second, that provision should be made for 20 days consumption of fuel, for we need not point out to our nautical readers the position of such a vessel in the broad Atlantic, minus her steam power, rigged as she is. What then becomes of the 1800 tons space for measurement goods? Supposing this vessel buffeted about for upwards of 20 days (as one of Cunard's superb vessels has been), she would require stowage for 103 tons $\times$ 20 days = 2060 tons of coals at the moderate computation of 8 lb. per horse per hour; if we reduce it to the minimum of safety, say 16 days stowage, we require 1648 tons. at 8 lb. per horse only; which we may say is the general average of the best and most economical boilers. We know enough of marine engineering to state confidently that the boilers of the Great Britain will not reach this point.

We hope we may not be misunderstood, and our remarks considered inimical; our desire is simply to correct what we believe to be erroneous conclusions and to put the proprietors on their guard, that they may be moderate in their expectations. It would conduce to our utmost pleasure if their most sanguine expectations become realized, not in the narrow spirit of pecuniary gain, but as a national triumph and convincing proof that Great Britain is, and ever shall be, mistress of the seas.

"THE LIGHT OF ALL NATIONS."

THE laudable attempt of Mr. Bush to construct a light-house on the Goodwin Sands, is now occupying public attention, we have, therefore, obtained the following particulars of the construction of the caisson and its progress, which we hope to be able to follow up in next month's Journal, with a drawing, and an account of the works as they progress. We are happy to hear that up to the present period, notwithstanding some severe gales and squally weather, Mr. Bush has proceeded very successfully, and fully equal to his most sanguine expectations. We sincerely hope that his praiseworthy efforts will be crowned with success.

The caisson, which is of cast iron, is 30 feet in diameter at the base, and is of a conical form, diminishing upwards 1 in 5. It is formed of a series of plates, with flanges at the joints 3 inches in width, and connected together by $\frac{1}{4}$ inch wrought iron bolts. Each tier of plates is 6 feet in height; the lower tier is $1\frac{1}{2}$ in thickness, the circumference is divided into 24 plates as are the other courses above, which are respectively arranged so as to break joint. Within the lower tier the working chamber is constructed, in which the process of excavation will be carried on as in a diving bell, and the spoil discharged through a 4-feet aperture in the centre of its domed top into the second chamber. The chamber above is fitted with air-pumps, gauges, and apparatus for regulating the supply of air to the workmen in the working-chamber; and from the second chamber proceeds a 4-feet cylinder extending upwards through the centre of the caisson for the further discharge of spoil. The height of the chamber above will be regulated by the depth to which it may be necessary to proceed before the chalk is arrived at, plates being added to the caisson as its descent is effected through the sand. By means of valves and man-holes, &c., the two lower chambers communicate with each other as far as it is necessary for the supply of air for the workmen, and the discharge of the sand during the process of excavation, which will be carried on from within, similar to the sinking of a shaft or the kibt of a well, the lower chamber acting in this respect as a diving bell, by which the work is carried on under water, and through the cylinder at stated periods, when external communication is cut off from the lower chamber, the spoil will be discharged into the sea. The caisson has now descended 24 or 25 feet in the sand, or about 30 feet below low water mark; the tide rises about eighteen feet, and from various indications combined with the general stability of the machine, it is presumed to rest at present near the solid chalk. When the caisson shall have been brought upon a level bed, and the sand excavated, the interior will be filled up with solid masonry and concrete, upon which foundation the light-house is proposed to be erected.

PATENT RELIEVO LEATHER HANGINGS.

We feel much pleasure in directing architects to the very great improvements made in Messrs. Leake and Co.'s *Patent Relievo Leather* hangings, panels, imitation oak carvings, &c., of which they have an endless variety at their offices, 52, Regent-street. Her Majesty and H.R.H. Prince Albert have more than once had a large variety of patterns sent to Buckingham Palace and Windsor Castle for their inspection; and have shown their excellent taste in selecting many beautiful examples, for decorating step of the state apartments both at Windsor and Buckingham Palace. The designs are very beautiful; indeed it is difficult to discover that some of the patterns are not *carvings in wood*—so closely imitated are the chisel marks, the grain of the wood, the undercutting, and its assimilation of colour to the best oak and walnut carving of the middle ages. The hangings, friezes, heads, fruits, &c., in the various rich and elaborate styles of decoration prevalent in Spain, Italy, France, and Germany, as well as our own Elizabethan, are here brought to their greatest perfection, and will bring about a decided improvement in our present mode of decorating public buildings, the baronial residences of our nobility, churches, &c. The cost of these ornaments is about half the price of carvings in wood.

IMPROVEMENT IN COATING OR COVERING METALS.

Mr. Henry Fox Talbot, of Laycock Abbey, Wilts, has obtained a patent for improvements in coating or covering metals with other metals, and in colouring metallic surfaces.—They are four in number. The first consists in adding gallic acid to the metallic solutions intended to be precipitated. Any convenient solution of silver, gold, or platina is taken: and to each of them is added a solution of gallic acid, in water, ether or alcohol, (the last being preferred.) Into any one of these mixtures a clean bright plate of metal is immersed until it becomes coated with silver, gold, or platina, as the case may be. A weak or dilute solution is recommended to commence with, and afterwards a stronger one. The acid need not be pure. The second is a method of silvering metallic surfaces. Freshly precipitated chloride of silver is dissolved in hyposulphite. Into this solution a clean bright plate of metal is immersed, and becomes very quickly coated with a bright silver coating. To obtain thicker coats of metal, a galvanic battery is employed, using one of the liquids before described, and taking for one of the poles a piece of metal of the same kind as that intended to be precipitated. The third is a method of ornamenting surfaces of brass or copper, by first gilding them partially, according to some pattern, and then washing them over with a solution of chloride of platina, which gives a dead black appearance to the rest of the surface, and enhances the brilliancy of the parts gilt. The fourth is a method of colouring polished surfaces of copper, by exposing them to the vapour of sulphuretted hydrogen, or any of the liquid hydrosulphurets, or to the vapours

of sulphur, iodine, bromine, or chlorine, or by dipping the metals into liquids containing them. The claim is to the use of the gallic acid, or any liquid containing it, or any analogous vegetable substance for facilitating the precipitation of metals upon other metallic surfaces, and coating them therewith—to the use of hydrosulphate of soda for the silvering of metals, and the employing a galvanic battery for obtaining thicker deposits of silver, gold, or platina, but only when used in conjunction with one of the liquids so described: and to the colouring of copper surfaces by exposing them to the chemical action of the above-named substances.

IMPROVEMENTS IN DAUGUERREOTYPE.

M. Claudet, of High Holborn, and Adelaide Gallery, has obtained a patent for improvements in the process for obtaining images or representations of nature or art. They are five in number. The first consists in making in the front of the camera obscura an aperture large enough to admit object glasses of various foci, so as to have either large or small plates, and obtain images of near or distant objects. The second consists in substituting for the detached mercury box ordinarily employed, a cup of mercury placed within the camera, and heated by a spirit lamp till the mercurial vapours rise and fill the camera. The light and mercury are made thus to act simultaneously on the plate, whereby a more intense and perfect image is obtained. In the side of the camera there is an eye-hole, covered with red or orange-coloured glass, through which the operator may watch the process, and be thus enabled to withdraw the plate the instant the proper effect is produced. The third consists in placing immediately behind the sitter for a portrait, painted back grounds or scenes, representing landscapes, interiors of apartments, &c., which, being thus brought within the range of the Dauguerreotype apparatus, are transferred to the plate, as well as the portrait of the sitter. The fourth consists in the employment, in the absence of daylight, of an artificial light, produced either from the combustion of coal, promoted by a jet of oxygen gas, or from combustible gases and carbureted liquids burning together with oxygen: or from a solid refractory body suspended in a jet of inflammable gas, &c. Care must be taken that the burner is fixed exactly in the axis of the reflecting mirror, or that the greatest light falls on the centre of the curve. The fifth and last improvement consists in performing the whole process in a lighted room instead of in the dark, as has been hitherto the case. A white light must, however, be avoided, and screens of red, orange, green, or yellow, are therefore employed. Of these colours red is preferred, as having the least injurious effect on the plates.

A NEW FORGING MACHINE.—This machine for the working or forging of iron, steel, &c., is quite portable, occupying only a space of 3 feet by 4 feet, and cannot be deemed other, even by the most critical judges than one as purely original in principle, as well as practical in its application. It may be worked by steam or water power, and when moved by the former at an exhibition it made 650 blows or impressions per minute; but from their very quick succession, and the work being effected by an eccentric pressing down, not striking the hammer or swage, not the least noise was heard. There are five or six sets of what may be called anvils and swages in the machine, each varying in size. The speed and correctness with which the machine completes its work, is perfectly astonishing, and must be seen in order that its capabilities in this respect may be duly appreciated: for instance, when it was put into motion for the purpose of producing what is known as a roller, with a coupling square upon it, (and which had to be afterwards turned and fluted,) the thing was accomplished in fifty seconds! of course at one heat, to the astonishment of the bystanders. But what appeared as the most extraordinary part of the affair, was, that the coupling square was produced direct from the machine, so mathematically correct, that no labour can make it more so! The machine will perform the labour of three men and their assistants or strikers, and not only so, but complete its work in a vastly superior manner to that executed by manual labour. For engineers, machine makers, smiths in general, file makers, bolt and screw makers, or for any description of work parallel or taper, it is most specially adapted; and for what is technically known as reducing, it cannot possibly have a successful competitor—in proof of which it may be stated, that a piece of round iron $1\frac{1}{2}$ inch in diameter, was reduced to a square of $\frac{1}{4}$ in., 2 ft. 5 in. long, at one heat. The merit of this invention belongs, it is said, to a gentleman at Bolton, of the name of Ryder.—*Leed's Mercury*.

IMPROVED DOOR KNOBS.—A patent has been obtained by Mr. Daniel Greenfield of Birmingham for improvements in manufacturing hollow metal knobs for the handles of door and other locks; the essential character of the improvement being that of forming an interior lining of stamped iron-plate to the hollow-ball part of the knob, and (in case it is preferred) an interior of cast-iron to the neck part of the knob, in order, by means of such stamped-iron and such cast-iron (if the latter be used) to give support to the brass, German silver, or other metal, whereof the exterior surface of such knob is or may be composed."

ENGINEERING WORKS.

SUSPENSION BRIDGE OVER THE DANUBE.

On the 24th of August, the ceremony of laying the foundation-stone of the suspension bridge now being erected across the Danube, to unite the cities of Pesth and Buda, was enacted. Of the gigantic work now in progress, two coffer dams, unequalled in cubical dimensions by any ever yet constructed, are now completed and water tight, being those on the Pesth side, whilst those on the Buda side are in an advanced stage. That destined for the sustaining pier on the Pesth shore was the scene of the display: it was fitted up as a vast saloon, with graduated seats all round it, to accommodate 2,000 people, with a "loge," or box, for the royal party. Shortly after 5 o'clock p. m. a discharge of artillery announced the departure of the Royal *cortège* from the Palatine's Palace at Buda, and in due time the Archduke Charles, descended the spacious stairs made in the framework of the dam, accompanied by the Palatine, his Archduchess, and their two children, the flower of Hungary's nobles, the magistrates and officials of the cities, aides-de-camp, and, amongst others, Mr. W. Tierney Clark, the engineer of this gigantic work. Their highnesses having reached their places, remained there to hear read, and to sign with others the inscription, in Hungarian, to be placed beneath the foundation-stone; which being done, it was, with the coins of the realm, placed by the engineer in its destined bed, and on a signal being given by him, the "traveller" (the machine for raising, lowering, and setting the ponderous masses of stone in such works) was moved forward from the other end of the dam, bringing with it a block of granite of about 90 cubic feet in size, and which, being lowered and fixed in its berth, the Archduke Charles was presented by the Baron Sina with a gorgeous and elaborately-worked gold and silver trowel (executed by Messrs. Mortimer and Hunt, of London) and mallet, and thereupon the usual ceremony of applying both to the stone was gone through by his Royal Highness, and then by the Palatine, his wife and children, the Primate, the magistrates of the city, the Baron Sina, the Count Stephen Ischenyi, and the engineer, which being communicated by the hoisting of a flag to those without, a response was given by a discharge of 25 cannon, and thus closed this interesting and splendid ceremonial. It is not the least interesting part to know, that this great work, is from the designs, and under the direction, of our distinguished countryman Mr. W. Tierney Clark, F.R.S., civil engineer, to whom the Archduke Charles on this occasion, in the name of the Emperor, presented a gold snuff box, with the cypher of the imperial donor emblazoned on it in magnificent and large brilliants. To Mr. Adam Clark, the resident superintendent of the work, his Highness presented a gold box, set in brilliants, and gave 100 ducats (£50) to be distributed amongst the men employed. The trowel, on which is a representation of the proposed work in basso relievo, with the mallet, has been handed over by the Archduke to the national Museum, as a memorial of the day and undertaking.

THE TELEMAQUE TREASURE SHIP.

The following extracts from a private letter in the *Times* will be found to contain much interesting intelligence respecting the raising of the *Telemaque*, which was sunk in the Seine, near Quillebœuf, about 50 years ago.

"My attention was attracted by a pile of timbers rising out of the river, at a short distance from the quay at Quillebœuf, on which a number of men, whom by the silent energy of their movements I recognized as English, were hard at work. These were the preparation for raising the treasure-ship. I was politely received by Captain Taylor, one of the chief adventurers in this speculation, and the conductor of the operations, who during my stay took pains to give me every possible information on the subject in which I was interested.

"It appears from minute examination by soundings and by divers, that the *Telemaque* is lying on her side on a bed of sand and rock, in about eight feet water at ebb tide, a drift of mud sloping the height of her deck, but on the other side half of her bottom above her keel is entirely clear. The parties who have hitherto attempted to raise her have proceeded on a plan which has often succeeded in tolerably smooth tidal waters. They have passed chains round the vessel at low water, carried the ends of these chains into two large barges moored at the head and stern of the *Telemaque*, and then expected that as the tide rose the barges would raise the sunken brig by the chains. But as the tide in the Seine rushes up in a sudden and lofty wave or bore, the barges were dashed up suddenly, and the chains were either disarranged, or, being unequally strained, broke.

"Captain Taylor has moored a barge near the wreck, and upon it he has established his head quarters. Thirty picked English workmen live there night and day, taking advantage of every favourable hour of the tide. In the barge they have their workshop, their forge, and berths, and kitchen, all quite man-of-war fashion. The first operations of this last undertaking were commenced by driving wooden piles pointed with iron, and on these piles a stage has been erected so as to form a solid superstructure or bridge resting over the *Telemaque*. Iron harpoons with barbed points were then driven right through the vessel, and chain cables were passed round the bow and the stern, and longitudinally from the stem to stern of the vessel. The next process will be to fix powerful screw-jacks, and then by them, slowly and evenly worked, to raise the brig.

"As soon as it is raised a few inches from the bed where it now lies, cable chains, worked by powerful capstans on shore, will be attached to it, and the wreck slowly dragged toward the quay into a position where it will be high and dry at low water.

OPENING OF THE SOUTHAMPTON DOCKS.—The tidal dock of this great national commercial undertaking was opened in the afternoon of Aug. 29th. The dock is said to be the largest in England, the inside, from wall to wall, covering an area of sixteen acres. It is excavated to that extent, that there will be always eighteen feet water at low water spring tides. The opening is 150 feet in width, thus admitting vessels of almost any tonnage. A shed is now building on the north-east side, 360 feet in length, and fifty feet wide in the floors, for the storage of goods, from which a tram-way leads to the railway station, distant about 300 yards. This dock was commenced three years ago (this month), at a cost of about £140,000., and had it not been for unforeseen causes, would have been opened for traffic some time since. The vessels belonging to the Peninsular and Oriental and the Royal West India Mail Company, will henceforth make use of it; and no doubt every vessel of consequence will take advantage of the facilities thus offered for landing and shipping goods. The latter company have contracted for the use of a portion of the dock for the sum of £2,000 per annum. There is another dock, now in progress, called the inner or wet dock. It is impossible to state when this will be finished. Want of funds prevents that accomplishment for the present. This dock covers an extent of fourteen acres, and is the nearest to the town.

BOULOGNE HARBOUR.—We understand it is definitively settled that our jetties are to advance 600 yards further into the sea, so that vessels drawing 12 feet water, will be enabled to enter them at all hours of the day and night. When they will be commenced is one question—but when finished is another. Our English readers must not imagine that we—no, not we, but the *Ponts et Chaussées*—have yet to learn how to go ahead by steam, as our unfortunate harbour too plainly demonstrates.—*Boulogne Gazette*.

COLCHESTER NAVIGATION.—The plan for constructing a ship canal from Wivenhoe to the Hythe, as laid before the public in Mr. Bruff's plan and report has, we understand, met with a very favourable reception among our trading community, who are of course the best judges of the merits of such a plan, and of the benefits derivable therefrom. The possibility of constructing such a work for a very moderate sum (Mr. Bruff states £56,000, exclusive of the land) gives it a powerful claim to public attention, and the advantages Colchester would derive from its establishment are obvious.—*Essex Standard*.

Newcastle-upon-Tyne.—The banks of the Tyne at Newcastle are very abrupt, and the breadth of the river about 620 ft., over which a timber bridge is projected on the plan of the viaducts on the Shields railway, the centre arch of which is intended to be 280 ft. span, and 100 ft. above high water at spring tides. The estimated cost is £100,000, proposed to be raised in 5000 20l. shares. The number of passengers per week traversing the present bridge is 170,000, one-third of which, it is expected, would pay toll: but the project does not progress. What a splendid opportunity here presents itself to adopt the use of iron to its fullest extent, especially as the price of that material is so unprecedentedly low, and the facilities of casting large pieces and quantities has so much increased.—*O. T.*

Whitby Pier.—This pier has been lengthened, and is now about half a mile long. In a very short time it will be open to the public, and we have no reason to doubt but that it will equal most of the piers in England.—*Hull Advertiser*.

STEAM NAVIGATION.

East India Steam Navigation.—The steamer *India* having performed her last voyage from Suez to Bombay against the height of the monsoon, a circumstance unprecedented in the annals of navigation, it may be interesting to compare a statement of that steamer's performance on her last two voyages, the first having been made in the fair season, and the second against the strength of the monsoon. On her first voyage the *India* left Calcutta on the 10th of January last, and steamed to Suez in 25 days and 14 hours, running 4,849 miles, or 182½ miles per day, consuming 680 tons of coal, or 7.6 lb. per horse power per hour. On her second voyage she left Calcutta on the 9th of May, and steamed in 34 days 4,658 miles against the wind, averaging 137 miles per day, and under sail four days; total distance 5,089 miles, consuming 900 tons of coals, or 7½ lb. per horse power per hour. This result is most important, as showing that the communication by steam can be kept up with the eastern side of India at all seasons of the year. On the first voyage the Calcutta letters reached London in 46 days; the second voyage her letters were detained 24 days in Egypt waiting a conveyance.—*Hants Independent*.

The James Watt.—Messrs Maudslays and Field have received orders from Government to proceed immediately with the engines of 800 H. P.

Cherokee.—The engines sent out to Canada for this vessel are from the manufactory of Messrs. Maudslays and Field.

FRENCH STEAMERS.

The following list of vessels is from the *Railway Moniteur*, with the ports at which they are being built, and the names of the engineers who are making the engines. They are 14 in number, of 450 H. P. each; the *Ulloa*, *Columbus*, and *Labrador* have been already launched, and it is expected that they will all be ready for sea in the course of next year.

NAME.	PORT.	ENGINEER.
Darien	Cherbourg	M. Cavé, of Paris.
Ulloa	Ditto	
Christopher Columbus	Brest	
Maellan	Ditto	
Cacique	L'Orient	Government Steam Factory at Indret
Eldorado	Ditto	
Carib	Ditto	
Canada	Brest	
Labrador	Toulon	M. Schneider, of Creuzot.
Orinoco	Ditto	
Albatross	Ditto	
Greenland	Rochefort	
Montezuma	Ditto	M. Hallette, of Arras.
Panama	Ditto	
Five War Steamers of 220 H. P. are also being built.		
Espador	Indret	M. Pauwels.
Caimar	Ditto	
Phoque	Bichwiller	M. Stehelin.
Glan	Ditto	
Cuvier	L'Orient	Miller, Ravenhill & Co. of London.

AMERICAN MAIL STEAM SHIPS.—The British and North American Royal Mail Steam Company's new steam ship *Hibernia* was launched at Greenock on Thursday 8th Sept. The *Hibernia* is about 200 tons larger and of greater power than the present mail steam ships. Captain Edward C. Miller, formerly of the *Acadia*, will now command the *Columbia*. If the new ship only equal, in general efficiency and speed, the four vessels composing the line, she will be a steamer of the first class. That she will equal, if she do not exceed them in those indispensable qualities, the skill and judgment of the managers of the company are sufficient guarantees.—*Liverpool Albion*.

The Hindostan.—This splendid vessel started from the Southampton Docks on the 24th ult. for Calcutta; she is destined for the navigation of the Indian Seas, between Calcutta, Ceylon, and Suez, and forms part of the intended fleet of the Peninsular and Oriental Steam Navigation Company for establishing a communication between England (from the Port of Southampton) and our Indian possessions, via Alexandria and Suez; between these two points the communication will be as heretofore, overland. This vessel was built by Messrs. Wilson, of Liverpool; her length of keel is 220 feet, length over all 250 feet, beam inside the paddle-boxes 39 feet, depth 30½ feet, burden 1,800 tons; engines, 550 H. P. constructed by Messrs. Fawcett & Co., the eminent engineers of Liverpool. She is fitted with Captain Smith's safety paddle-box boats, which are so large that the whole of the crew and passengers could be taken in them in any sea. She has also four large quarter boats and stern boat. She is divided by wrought-iron water-tight bulkheads into five compartments. In our next number we shall give some further particulars of this splendid vessel.

Gloucester and Ledbury Canal.—The feeder at Canon Froome, for supplying the canal with water, has now been put in operation. It is expected that in two months boats will be able to come up to Castle Froome.—*Hereford Journal*.

Portsmouth.—A new steam-frigate called the *Firebrand*, was launched at this dock-yard on the 5th inst. She was immediately taken into dock to be coppered, and will, as soon as fitted with her engines, be commissioned. Her original name was the *Beelzebub*, but when the *Firebrand*, after bringing over the King of Prussia to this country, had her name altered and was called the *Black Eagle*, the *Beelzebub* was changed to the *Firebrand*. Two other first class steamers are building at this dock-yard called the *Scourge* and *Centaur*.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM THE 31ST AUGUST, TO 22ND SEPTEMBER, 18 2.

Six Months allowed for Enrolment, unless otherwise expressed.

CHARLES FREDERICK GUITARD, of Birchin-lane, notary public, for "improvements in the construction of railways."—Sealed August 31.

CHARLES THATCHER, of Midsomer Norton, Somerset, brewer, and THOMAS THATCHER, of Kilmerston, in the said county, builder, for "improvements in drags or breaks to be applied to the wheels of carriages generally."—August 31.

ROBERT HAZARD, of Clifton, near Bristol, for "improvements in ventilating carriages and cabins of steam-boats."—September 3.

WILLIAM ROCHE, of Prince's-end, Stafford, mechanic and engineer, for "improvements in the manufacture of mineral colours."—September 3.

WILLIAM WARBURTON, of Oxford-street, gentleman, for "improvements in the construction of carriages and apparatus for retarding the progress of the same."—September 8.

JOHN WORDSWORTH ROBSON, of Jamaica-terrace, Commercial-road, engineer, for "improvements in machinery and apparatus for raising, forcing, conveying, and drawing off liquids."—September 8.

JAMES INSOLE, of Birmingham, saddlers' ironmonger, for "improvements in the manufacture of brushes."—September 8.

JOSEPH HENRY TUCK, of Francis-place, New North-road, engineer, for "improvements in machinery or apparatus for making or manufacturing candles."—September 8.

WILLIAM EDWARD NEWTON, of Chancery-lane, civil engineer, for "improvements in machinery or apparatus for making or manufacturing screws, screw-blanks, and rivets." (A communication.)—September 8.

HERBERT GEORGE JAMES, of Great Tower-street, merchant, for "improvements in machines or apparatus for weighing various kinds of articles or goods." (A communication.)—September 8.

WILLIAM FOTHERGILL COOKE, of Copthall-buildings, Esq., for "improvements in apparatus for transmitting electricity between distant places, which improvements can be applied, amongst other purposes, to apparatus for giving signals and sounding alarms at distant places by means of electric currents."—September 8.

THOMAS THIRLWALL, of Low Felling, Durham, engine-builder, for "improvements in lubricating the piston-rods of steam engines, and of other machinery."—September 8.

WILLIAM CROFTS, of New Radford, Nottingham, lace machine maker, for "improvements in the manufacture of figured or ornamental lace."—September 8.

THOMAS MARSDEN, of Salford, Lancaster, machine maker, and SOLOMON ROBINSON of the same place, flax dresser, for "improvements in machinery for dressing or hackling flax and hemp."—September 8.

JAMES WAKE, jun., of Goole, York, coal factor, for "improvements in propelling vessels."—September 9.

JOHN ROLT, of Great Cumberland-place, colonel in Her Majesty's army, for "improvements in saddles."—September 15.

FREDERICK BOWLES, of Moorgate-street, London, for "a new method by machinery of preparing flour from all kinds of grain and potatoes, for making starch, bread, biscuits, and pastry." (A communication.)—September 15.

CHRISTOPHER NICKELS, of York-road, Lambeth, gentleman, and CALES BEDELLS, of Leicester, manufacturer, for "improvements in fabrics produced by lace machinery."—September 15.

WILLIAM HENRY JAMES, of Martin's-lane, London, civil engineer, for "improvements in railways and carriage ways, railway and other carriages, and in the mode of propelling the said carriages, parts of which improvements are applicable to the reduction of friction in other machines."—September 16.

JOHN SANDERS, WILLIAM WILLIAMS, SAMUEL LAWRENCE TAYLOR, and WILLIAM ARMSTRONG, all of Bedford, agricultural implement makers, and EVAN WILLIAM DAVID, of Cardiff, for "improvements in machinery for ploughing, harrowing, and raking land, and for cutting food for animals."—September 22.

PATRICK STREAD, of Halesworth, Suffolk, malster, for "improvements in the manufacture of malt."—September 22.

JOHN JUCKES, of Putney, gentleman, for "improvements in furnaces."—September 22.

Mr Peter Ewart.—We very much regret to announce the death of Mr. Peter Ewart, of Woolwich Dockyard, many years chief engineer in the Government service, to whom was entrusted the direction of the marine and mechanical engineering establishment at Woolwich; his death was occasioned by a serious accident on the 8th ultimo. Mr. Ewart was present at the testing of a chain cable in the proof-house, when the cable suddenly broke, and a portion of it flying back struck him a violent blow on the body, by which he was driven with great force against the wall of the proof house.

TO CORRESPONDENTS.

Communications received from O. T. on earthwork and suspension bridges.—J. W. S. of New York.—Mr. Hartop.—Mr. W. Gartland.—Mr. E. B. Rowley, and Mr. Pring.

A correspondent is desirous of knowing the maker's name of iron houses. Phoenix.—We are collecting materials for forming a table of the proportions of all our large steam ships and boilers, pressure of steam, &c., and will thank him, or any other correspondent if they will favour us with any information they may possess upon the subject.

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant, addressed to the Editor, No. 10, Fludger Street, Whitehall.

No. 2 has been reprinted and may now be had of the Publishers.

Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume.

THE PENNSYLVANIA CANAL AQUEDUCT,

(With an Engraving, Plate XIII.)

(FROM THE AMERICAN JOURNAL OF THE FRANKLIN INSTITUTE.)

Description of the Wooden Aqueduct carrying the Pennsylvania Canal across the river Alleghany, at Pittsburg; from actual measurement. With remarks by JOHN C. TRAUTWINE, Civil Engineer, of Athens, Tennessee, U.S.

THIS aqueduct was built in the year 1829, by Mr. Lothrop, of Pittsburg, at an expense to the State of 104,000 dollars. It has two abutments and six piers of stone, and seven arches of timber of 150 feet clear span each; the whole length of the aqueduct between the abutments being 1092 feet. The masonry is of cut ashlar, in large courses, with rubble filling. The material is a gray sandstone, rather too soft, in my opinion, for such parts of a structure as are exposed to rapid currents, bringing down heavy fields of ice and drift wood, as is the case with the Alleghany. The piers are 7 feet thick on top; they batter one inch to a foot on the sides, are semi-circular at their down-stream ends, and are provided with break-water starlings. The average height of the piers is about 40 feet.

The timber of the aqueduct is white pine, with the exception of the chords and the pier-posts, which are of white oak, as being better calculated to resist the great strains that come upon them. I conceive, however, that any precaution of this kind would apply with more force to the pole plates, or cap-pieces, as it is well known that the resistance of timber to compression is much less than that to extension. Therefore, if extra precautions are requisite for the chords, they are doubly so for the poles.

The width of the aqueduct, from out to out of weather boarding, is about 34 feet. The height of the trusses, from bottom of chords to top of poles, 16 feet. The canal trunk has a top width of 16 feet, a bottom width of 15 feet, and a depth of 5 feet. The depth of water is generally 4 ft., sometimes 4 ft. 3 in. There are four trusses to each span. These particulars, however, with the other principal dimensions, are so plainly indicated by the drawings as to require no farther explanation. Throughout the drawings, the same letters refer to the same parts.

SCANTLINGS OF THE PRINCIPAL TIMBERS AND IRONS.

Arch pieces, 7 × 14 in., L, six to each truss, or composing each rib.

Pole plate or cap, J, of inner trusses, 10 × 15 in.

Ditto, F, of outer trusses, 10 × 12 in.

Chords, C, of both inner and outer trusses, each in two pieces, each piece 7 × 15 in.

Queen posts, Q, in body, 9 × 10 in.

Ditto, in heads and feet, 10 × 14 in.

Main braces, S, 8 × 10 in.

Counter braces, X, 8 × 4½ in.

Butting pieces, P, at heads of queen posts of outer trusses, 5 × 7 in.

Ditto, T, or straining pieces at heads of queen posts of inner trusses, 5 × 7 in.

Diagonal braces, U, in roof, and under canal truck, 6 × 7 in.

Extra braces, M, on outer trusses only, 6 × 12 in.

Straining sills to ditto, k, 6 × 10 in.

Straining pieces to ditto, f, 6 × 12 in.

Straining sills to pier posts, j, 6 × 10 in.

Fishing pieces to poles, b, over piers, 6 × 12 in.

Roof tie beams, E, 7 × 12 in.

Floor girders, G & H, 9 × 18 in.

Additional pieces, A, under girders marked G only, 9 × 15 in.

Plank, of footway, towpath, and canal trunk, thickness 3 in.

Weather boarding, N, thickness ½ in.

Iron suspending rods, R, 1½ in. diam.

Screw bolts, 1 in. square; spikes for planking of canal trunk, ½ inch square; spikes at heads and feet of braces, ½ in. square.

In Fig. 1 it will be seen that the tops of the lower girders are not all in the same horizontal line, but that every other one, H, is raised about one foot above the intermediate ones, G. When the aqueduct was first built, only one of these sets of girders was employed, being supposed sufficient to sustain the weight of water in the trunk. Their distance apart was about ten feet in the clear. But when the water was let into the trunk, the girders began to yield under a head of about three feet, and it was found necessary to double their number, and moreover to bolt, or rather stirrup, to every alternate one, viz. those marked G, an additional under-girder, A, Figs. 2, 3, and 4.

The reason for thus alternately raising and depressing these lower girders was, to permit the passage of the two courses of lower diagonal braces from one H to another, over G, (see Fig. 9, and also the dotted lines *a, a, a*, in Fig. 3). Where the H's cross the inner chords, (which are lower than the outer ones,) they are made to bear on them, by means of the blocks *h, h*, Fig. 3. These blocks are not shown in the transverse section, it being supposed to be taken near one of the girders, G. Over the girders, G, are seen (Fig. 3,) blocks *O, O*, marked in dotted lines; there are transverse timbers, resting on G, and helping to support the flooring plank of the canal trunk, as there are no longitudinal joists in the aqueduct. The pieces *O*, do not interfere with the diagonal braces, merely running from each inner chord to the braces.

The floor of the trunk rests only on the upper course of diagonal braces, on the transverse pieces, *O*, and on the raised girders H.

Each girder, H and G, is sustained by the two inner chords, and by four suspending rods of iron, 1½ in. in diameter, of which two are shown in Fig. 4, by R, R. In the outer trusses, the tops of these rods bear on the tops of the arches, or curved ribs, (see Fig. 1,) by means of wooden saddle pieces, D, Figs. 3 and 4. In the inner trusses, they bear upon the tops of the poles, or caps, and are covered by a longitudinal capping piece, of 3 in. thickness (*m*, Fig. 4); this capping is rounded off at top, so as to prevent the chafing of the tow-rope.

To bring the bearing of the suspending rods more equally on all the arch-pieces, blocks are inserted between the arch-pieces, vertically, at the place of each rod, as shown in Fig. 3. *M, M*, in Fig. 1, are extra braces, employed only in the outer trusses; *k, k*, are their straining sills. At their upper ends they abut against short pieces of 6 × 12 (*f, f*) firmly bolted to the poles. These extra braces are in pairs, being on both sides of the poles.

j, j, Fig. 1, are the straining sills for the pier braces, S, S, serving to stiffen the pier posts; see Fig. 6, which also shows the cast iron abutment plates, *g, g*, for receiving the feet of the curved ribs. They are merely flat plates, 3 ft. 8 in. deep, 2 ft. wide, 2 in. thick, and without any flanches. The recess in the pieces, for receiving the feet of the ribs, and pier posts, is but eight inches deep. See also Fig. 2.

P, Figs. 3 and 4 are the short butting-pieces for relieving the heads of the queen posts from the action of the main braces. In the inner trusses, instead of these short butting-pieces, long straining-pieces, reaching from one post to another, are used, T, Figs. 3 and 4. T is represented in Fig. 3, to save the trouble of another engraving.

The suspending rods are about 5 feet apart; but it is seen in Fig. 1 that these rods stop short within some fifteen feet of the piers, because the curve of the ribs in that interval would not allow of the passage of girders past them. In this interval, therefore, the ends of the girders are supported by pieces, K, Fig. 7, bolted to the ribs.

s, s, Figs. 2 and 4, are uprights, placed 4 ft. apart, for spiking the side planking of the canal trunk to; at their heads they tenon into a continuous cap-piece, *v*, and at their feet they tenon between the strings *e* and *n*. *n*, and the blocks *t*, being supported by the queens, prevent *s* from spreading outwards.

Where the curve of the arches comes below the line of *t*, the latter is dispensed with, and *v* rests against the arches themselves.

r, r, are two pieces, of 3 × 6 in. spiked to the queens, for receiving

the floor plank of the tow-path, on one side, and of the footway for ordinary purposes, on the other.

The roof is boarded and shingled.

Where the tops of the inner arches get below the line of the tow-path floor, a piece of plank on edge resting on the floor is nailed against the queens, to prevent horses from slipping into the canal trunk.

Fig. 5 shows an excellent device for counteracting, to some extent, the tendency which trusses always have to settle in the centre. The poles or caps of the adjoining arches are here connected by fishing splices, each composed of two pieces of 4×12 in. well bolted, and trenailed together, through the caps; and as a further security, two blocks, *z, z*, of hard wood, about 4 inches square, are driven through from side to side. By the introduction of these splices, it is obvious that the inward draw of two adjoining trusses is mutually counteracted to a considerable extent. This arrangement, together with the extra braces, serves very much to stiffen the trusses, and something of the kind should always be resorted to in large spans.

Fig. 8 shows the mode of scarfing the pieces composing the curved ribs. These pieces break joint where the ribs pass the queens, so that the bolts of the scarfs pass entirely through the queens, and the rib pieces on each side of them. The scarf of the poles is shown in Fig. 3; that of the chords is the same as that of the poles, only that which constitutes the side view of the pole scarf, forms the top, or plan, of that of the chord.

Fig. 11. As it is always a matter of importance in a bridge erected over a stream liable to freshets, to secure each span as soon as possible, so as to stand in case the scaffold should happen to be carried away, the introduction of the secondary timbers is generally deferred until those essential to the support of the bridge, in such an event, are put together. Therefore, the diagonal braces are not inserted until after the girders are put into their places.

As these braces are tenoned into the girders at both ends, they could not be inserted into the mortises in the girders, unless some play were allowed at one end; this play is afterwards filled up by a pair of double wedges, as shown in Fig. 11.

Where the counterbraces of the trusses intersect the main braces, the former are merely tenoned into the latter, as shown in Fig. 3, at Y. Where the chords and queens intersect, they are notched equally into each other, so as to bring the two pieces composing the chords within about an inch of each other, Figs. 2 and 4.

The planking of the canal trunk is single, and well caulked. The courses of plank are from six to fifteen inches wide.

Remarks.—This aqueduct evinces, more strikingly than any other structure I know of, the capability of timber for the purpose of bridge building. The weight of water in the canal trunk on a single span, when 4 ft. 3 in. deep, amounts to 275 tons, of 2240 lb.; and we may safely say that that weight is frequently increased to at least 300 tons, during the passage of boats; for although a boat, of course, displaces a bulk of water of equal weight with herself, yet it may readily be conceived that the water so displaced does not instantaneously leave the span, on her entrance; and I think we may assume that at least 25 tons of it are frequently on a span at the same moment with the boat. Yet on a most critical examination, made with that view, I could not detect in any part of the timbers the slightest symptom of what might with propriety be called crushing. Slight compressions, (if I may be allowed to draw such a distinction,) were visible at the heads of the queen-posts, but not to a greater extent, apparently, than invariably attends all trusses of this kind in common bridges of large spans, after having been some time in use. In all bridges there is a tendency to settle, or sag, in the centre; and this tendency, of course, brings a heavy compressing strain upon the pole plates; but beside this compression, incident to the truss considered as a whole, there is another, acting at the several points at which the heads of the posts tenon into the poles. This compound compression explains a fact for

which I was for some time at a loss to assign a satisfactory reason. I have already stated that in the inner trusses of this aqueduct, a straining-piece, like that shown at T, fig. 3, was inserted between the heads of the posts, in preference to the short butting piece, P, figs. 3, 5, employed in the outer trusses. This was evidently done under the impression that it opposed a more perfect resistance to the compressions alluded to, than the shorter pieces; and, at first sight, it will probably strike most of my readers in the same manner. But it is of great importance to know, that although the long piece is almost invariably introduced, both by engineers and bridge builders, whenever extraordinary compression of the pole is anticipated, it is in fact entirely ineffective; whereas the short butting pieces perform the duty assigned them perfectly,

I shall endeavour to point out the cause of this.

The compression of the poles evidently increases from the piers towards the centre of the span, in the same manner as in a single long piece of timber, supported at two ends, when it sags in the middle: consequently, when the bridge settles, as it always will, more or less, the head of any one post is moved a greater distance towards the centre of the span than the post behind it, that is, between it and a pier. Therefore, the opening, *p'*, behind the post, *Q'*, must be a little wider than the opening *p*, behind the post *Q*; and, consequently, the inner end of the straining-piece, T, cannot be forced up into contact with the head of the post *Q*, but must remain distant from it an amount equal to the difference of the compression which takes place in that part of the pole between *Q'* and the centre of the span, and that part which extends from *p'* to *p*. This difference in the amount of compression between any two consecutive posts, is very perceptible in all large bridges, being generally about $\frac{1}{4}$ of an inch, that is if there be 7 spaces in the truss, between a pier and a king post, the opening at the inner one will generally be about $\frac{1}{4}$ of an inch, at the next one $\frac{3}{8}$, at the next $\frac{1}{2}$, and so on to the queen post near the pier, where it will diminish to nothing. In some bridges, and those excellent ones, I have seen the openings behind the queen posts much greater than this, at least double; but, I believe, only in such bridges as have no chords to confine the feet of the ribs. Of course some portion of these openings, in every case, is due to the compression which takes place in the heads of the posts themselves. This is frequently very perceptible. I could just detect it in a few of the queen posts of the aqueduct.

But it may be objected that if the explanation I have given be correct, then even the short butting piece, P, should also be ineffective; because, if the compression of the pole increases so perceptibly towards the centre, then supposing the length of the butting piece to be $\frac{1}{4}$ of the distance between two queens, the inner end of the butting piece should not come into contact with the pole, by an amount equal to $\frac{1}{4}$ of the opening which occurs between these two queens. Plausible as this deduction would seem, it is, nevertheless, incorrect, for as I have before remarked, the short butting pieces act admirably, and, as I conceive, for this reason, that although the entire length of that portion of a pole, or cap, between two adjacent posts, is in a state of compression, which, considering the whole truss as one great beam, gradually increases towards the centre, still the action of the main braces against the back part of the head of each post, tends to bring an additional strain upon the portion of the pole next adjoining the inside of the post head. This additional strain produces a compression of its own, which, unlike that operating on the truss considered as a whole, decreases towards the centre. Therefore, that part of the pole into which the head of any post tenons, is more compressed than the part at the end of the butting piece, and, consequently, the latter is brought into full action.

This matter is a very important one, and my remarks on it were suggested by seeing that in this aqueduct the long straining-piece had superseded the short butting piece, evidently in expectation of its greater efficiency. In the Market street bridge, at Philadelphia, the

finest in existence, the same defect exists; also in the viaduct of the Columbia and Philadelphia Railroad, near Philadelphia, and many others, built by the most talented and experienced bridge builders in the country.

But in all these bridges, as well as in this aqueduct, the inner ends of none of these long straining pieces are in contact with the heads of the adjoining posts, against which they were intended to exert a powerful compression. Consequently, they are not only useless, but positively injurious, as they add unnecessarily to the weight of the truss, and thus absolutely increase that tendency to settle, which they are intended to prevent.

I noticed a splintering, or spalling off, of the stones supporting the feet of some of the arches. The stones in this part of a bridge, as well as those forming the facing of the startings, should always be of good quality; and, in the former case especially, attention should be paid to their toughness; soft sandstone should never be admitted.

In an extreme case like this, of such an immense weight and so soft a stone, or indeed with stone of the best quality, I should certainly prefer to have the recesses in the top of the pier for receiving the feet of the curved ribs and pier posts, somewhat deeper than in this instance, where they are but 8 in. deep, figs. 1, 2, and 6. The pressure on the piers and abutments, so long as the bridge maintains itself, is almost altogether vertical, and as it sometimes happens that the bearing is not very fair, every precaution should be used to prevent spalling. One of the spans, at the time I saw the aqueduct, was (in my opinion,) in imminent danger of falling, in consequence of this.

I am confident that 2 trusses, instead of 4, would have been sufficient to support the trunk of this aqueduct, especially if another arch-piece had been added to the depth of the curved ribs, and the height of the trusses made a little greater. This additional height would, moreover, have added to the convenience of passengers on the roofs of the boats, who are now obliged to stoop in passing through the aqueduct. As the use of but two trusses would, of course, increase the clear width between them, to admit the tow-path, the girders might be trussed by a heavy arch-piece, which would insure abundant strength. A considerable diminution of expense would attend such an arrangement.

As to the piers of this aqueduct, they are, as before stated, but 7 ft. thick on top, or $\frac{1}{12}$ part of the span; or not quite $\frac{1}{4}$ as great as the proportion of those used in the Trenton bridge, which is the boldest one cited by Tredgold, in his table of stone piers for wooden bridges.

The foundations of the piers of the aqueduct do not appear to have settled in the least, or to have undergone any derangement; still, even in the face of this precedent, I should certainly prefer the foundation to be laid at the depth of a few feet below the bottom, in structures so important as this. There are, however, several bridges across the Alleghany, in the vicinity of the aqueduct, and all their piers are founded in this manner, (some of them, indeed, having but one course of timbers in their platforms,) which is strong evidence of the sufficiency of the plan, on a gravel bottom, even when exposed to tremendous freshets.

Viewed as a whole, this aqueduct, for which, I am under the impression, there was no precedent, certainly reflects the highest credit on Mr. Lothrop, for boldness and mechanical skill.* There are others,

of much the same kind, on the canal; all, I believe, designed by him. The general arrangement of the timbers is not original with him, having been long before practised, in very many instances, in common bridges; but the application of it to the purposes of so extensive an aqueduct, was certainly a very bold step; and its entire success is proof of an intimate knowledge of what he undertook.

I look upon this arrangement of timbers as the best yet devised for large spans. It certainly admits of many improvements in its details, and from some experiments of my own on the subject, I am under the impression that considerable modifications in some of the more important parts, might be made with advantage. I may take occasion, in some future paper, to allude to them.

The curved rib, it is well known, is stronger in the centre than at any other point; or, in other words, a load, which, applied between the centre and one of the piers, would destroy the rib, might be supported, with perfect safety, in its centre. But the truss which is connected with the ribs, is weaker in the centre than at any other point; its resistance to a load acting at any point, being, as in the case of a single piece of timber, proportional to the rectangle of the distances from the point at which the load is applied to the points of support. Therefore, the combination of the curved rib with the truss, secures a more uniform degree of strength throughout the whole span, than could be attained by either one, used separately.

But besides this, another very important consideration attends the combination of the curved rib with the truss, viz: that each not only contributes its own share to the support of the load, but actually increases the power of resistance of the other—that is, the two combined will support a greater load than they could separately, were the load divided between them. A curved rib, when employed by itself, is very weak at the haunches, and readily yields to a load applied there; but if proper means be adopted for preventing the rib from changing its form, its strength is wonderfully increased, indeed to such an extent that actual crushing of the timber must take place before the rib will yield to its load. Without this precaution, its flexibility will permit it to bend, and fall through between its abutments, under a load many times less than that necessary to crush it. Such a change of form, or bending, is prevented by the truss, and thereby so great an accession of strength is imparted to the rib, that if we could conceive the truss acting only in this capacity of a stiffener to the rib, without itself sustaining any portion of the load, still the strength of the bridge would be increased many fold. I have seen curved ribs of 200 ft. span, bend, and fall into the river, between their abutments.

The highest known freshet of the Alleghany, rose to about the floor line of the canal trunk; the weather boarding of the outside formed a kind of dam, against which, trees, barns, houses, &c., accumulated, until they formed a wide field of drift on its upper side. A large concourse of people stood on the banks of the river, expecting to see the whole structure lifted off from its piers, and floated away; but it stood perfectly firm, and I believe sustained no injury whatever.

Engineering Science.—The tunnel on the line of the Sheffield and Manchester Railway will be 3 miles in length, upwards of 600 ft. below the surface or summit of the hill at its greatest height, and in rock formation throughout its entire length. The works were projected and commenced upwards of 2 years ago, under the direction of Charles Vignoles, Esq. Five shafts were opened, at about half a mile distant from each other, for the purpose of proving the formation, of facilitating the driving of the drift-ways, and ultimately, of ventilating the tunnel. Whilst these were in progress, the drift-ways were carried on from each side, or face, of the mountain: the distance, or length, driven, on the eastern side, extending to nearly 1,000 yards, and from the next shaft 180 yards. The junction between these two portions of the drift-way was effected on the 17th Sept., and the levels, when checked, on a tie-bench, at the point of meeting, had varied but 9 decimals, or 1 in. nearly, and the range was within less than 2 in. of being geometrically true.—*Weekly Papers.*

* We think it proper to remark here, that in the 6th volume of the London Repertory of Arts, p. 220, is detailed at length, the specification of a patent taken out in England, in 1796, by Mr. James Jordan, for constructing aqueducts and bridges, with curved ribs of timber, or iron, and suspending therefrom, by iron rods, the floor or trunk, as the case may be. The celebrated bridge over the Delaware, at Trenton, commenced in 1804, is, in its general outline, almost a precise copy of the plate illustrating Jordan's patent, in the Repertory of Arts, and is, in principle, unquestionably an infringement of that patent. Mr. Jordan also gives a plate of a projected aqueduct, precisely the same in its essential principles as that which forms the subject of the above paper.

A FEW OBSERVATIONS ON THE FLY-WHEEL, AND ITS APPLICATION TO THE STEAM ENGINE.

THIS admirable collector and distributor of power, is so important a feature of the steam engine, that too much attention cannot be given to determine the proportion best calculated, to insure a sufficient degree of regularity in its motion, to answer general purposes; it is at the same time equally important to avoid all superfluous weight in its rim, because this imperfection not only creates unnecessary expense in the construction, but also occasions a portion of the effective power of the engine to be sacrificed, to keep the useless mass in motion.

In order to obtain the degree of regularity of motion which is in most cases requisite, the energy of the rim of the fly-wheel must be so proportioned to the power exerted by the piston, as to prevent the constantly varying effect of the power of the steam communicated through the crank, from sensibly affecting the regularity of the motion of the fly-wheel.

The same amount of regularity is not always required, and frequently, steam engines are applied to drive machinery of such a description, as will to a certain extent, equalize the irregular action of the steam through the crank; a corn-mill for instance, requires much less fly-wheel than would be indispensable for a cotton, or flax mill, because the energy of the mill stones, produces the same kind of effect as is produced by the fly-wheel itself, and in some cases, when fly-wheels are directly attached to the machinery driven, they might be made sufficiently powerful to dispense with the engine fly-wheel altogether, in as far as regularity of motion is concerned; but if advantage were taken of this circumstance, very great strain would be thrown upon all the mechanism between the crank and the fly-wheel of the machinery driven, which being frequently considerable, would be rapidly destroyed. A fly-wheel may therefore be considered in most cases indispensable in, or very near the engine-room.

Having had considerable experience in the construction of steam engines, under circumstances which enabled me to establish a regular scale of proportions, between the length of stroke and the relative diameter, speed, and energy of the rim of the fly-wheel, and the following rules having been put to the test of many trials, I am induced to submit this paper for insertion in the *Journal*.

The following table will show the length of stroke, the speed of the piston, the number of double strokes per minute, the diameter, circumference, and speed of the fly-wheel, which I have adopted, and upon which many of the following rules have been established.

TABLE A.

H. P.	Length of Stroke = S.	Speed of piston per minute = W.	Number of dble. strokes of engine per minute.	Diameter of fly-wheel = S × 3.82.	Circumf. of fly-wheel = S × 12.	Speed of the rim of the fly-wheel per sec. = $\frac{W}{10}$
	ft. in.	ft.	No.	feet	ft.	ft.
2	2 0	150	37.50	7.640	24	15.
4	2 4	157	33.64	8.913	28	15.7
6	2 8	164	30.75	10.186	32	16.4
8	3 0	171	28.50	11.460	36	17.1
10	3 4	178	26.70	12.733	40	17.8
12	3 8	185	25.22	14.006	44	18.5
14	4 0	192	24.00	15.280	48	19.2
16	4 4	199	22.96	16.553	52	19.9
18	4 8	206	22.07	17.826	56	20.6
20	5 0	213	21.30	19.100	60	21.3
23	5 4	220	20.62	20.373	64	22.
30	5 8	225	19.85	21.646	68	22.5
35	6 0	230	19.16	22.920	72	23.
40	6 4	235	18.55	24.193	76	23.5
45	6 8	240	18.00	25.466	80	24.
50	7 0	245	17.50	26.740	84	24.5
60	7 4	248	16.91	28.013	88	24.8
70	7 8	251	16.37	29.286	92	25.1
80	8 0	254	15.87	30.560	96	25.4
90	8 4	257	15.42	31.833	100	25.7
100	8 8	260	15.00	33.106	104	26.

The dimensions and weight of the rim of the fly-wheel, may be determined by the following rules; (note—in the calculation of the energy of fly-wheels, the boss and arms are not taken into consideration, they should be made as light as prudence will permit.)

Rule 1. To determine the mean diameter of the fly-wheel, measured in the middle of the breadth of the rim.

Multiply the length of stroke of the engine by 3.82, the product will be the diameter of the wheel, measured in the middle of the breadth of the rim.

The above proportion being adopted, will determine the following relative conditions.

1st. *The rim of the fly-wheel will run 20 feet per second, when the piston travels 3½ feet per second; or in other terms,*

2nd. *The speed of the rim of the fly-wheel, will be to the speed of the piston as 6 : 1; (note—this is not mathematically correct, because for the mean speed of the piston to be 1, when the speed of the middle of the rim of the fly-wheel is 6, it would be requisite that the half circumference of the fly-wheel should be 6, when the radius of the crank is 0.5, in which case the circumference of the fly-wheel being 12, the piston for one revolution of the wheel would make a double stroke = 2 feet, or twice the length of stroke, so that when the stroke = 1, the circumference of the wheel should be 12, and its diameter necessarily $\frac{12}{3.1416} = 3.8197$, &c., which should be the constant multiplier, instead of 3.82 that, with a view of avoiding useless decimals, I have adopted, the difference resulting therefrom being of no practical importance, since the multiplier 3.82 gives 6.0004 to 1 instead of 6 to 1.)*

3rd. *The circumference in feet of the fly-wheel, will be equal to the length of stroke of the piston in inches.*

4th. *The speed in feet per second of the middle of the rim, will be exactly one tenth of the speed of the piston in feet per minute.*

Area of cross section of the rim of the fly-wheel. Ten square inches area of cross section of rim, will answer very well when the periphery of the rim of the wheel travels at the rate of 10 feet per second, and could be adopted as a constant area for that speed, if the effective load per H. P. on the piston, was a constant load for every engine; this would be the case if the stroke for every power was the same, but the speed increases with the power of the engine, and the load on the piston varies inversely as the speed, so that the above proportion being determined for an effectual load per H. P. of 155 lb. on the piston, when travelling at the rate of 213 feet per minute, which load and speed are those of a 20 horse engine—then the effective load or the speed at which it travels, must be taken into consideration in the calculation, for, with an uniform load and speed as above determined, the section of the rim in square inches per H. P., would be found by multiplying the square of 10 feet per second, or 100 by 10 square inches, and dividing the product by the square of the true velocity of the rim, the cross section of which is to be found, or in more simple terms, by dividing the constant number 1000, by the square of the true velocity per second, of the rim, the cross section of which is required.

But as the load and speed vary with the power of the engine, it will be requisite to multiply the above quotient by 21.3, the standard velocity of the rim in feet per second, and to divide the product by the true speed in feet per second of the rim, the cross section of which is required, the quotient will be its area in square inches per H. P.

Therefore when V = True speed of the rim in feet per second.

V² = Square of ditto.

A = Area of the cross section of the rim in square inches per H. P., we shall have

Formula 1.

$\frac{10^2 \times 10}{V^2} \times \frac{21.3}{V} = \frac{10^2 \times 10 \times 21.3}{V^3} = \frac{21300}{V^3} = A$, from which results,

Rule 2. To find the area in square inches per H. P. of the

section of the rim of a fly wheel, its diameter and velocity being determined by Rule 1.

Divide the constant number 21300 by the cube of the velocity in feet per second, the quotient will be the area in square inches per H. P.

Example. What will be the area in square inches per H. P. of the rim of the fly-wheel of a 20 H. E., the velocity of which taken in the middle of the rim is 21.3 feet per second?

$$\text{When } V = 21.3$$

$$V^3 = 9663.597$$

$$\text{then } \frac{21300}{V^3} = \frac{21300}{9663.597} = 2.2 = \text{area per H. P. in square inches.}$$

For corn mills, saw mills, and other machinery not requiring great regularity of motion, or which by its own peculiar character tends to equalize the effect of the steam, 7 square inches of cross section may be allowed instead of 10, and will be found to answer very well; on such occasions the constant number 21300, will be reduced to $10^3 \times 7 \times 21.3 = 14910$, and the formula No. 1 would be $\frac{14910}{V^3} = A$

= Area of cross section of rim in square inches per H. P.

The area of the cross section of the rim of the fly-wheel being obtained as above, the total weight of the rim per H. P. will be found by multiplying the area in square inches by the circumference of the wheel in inches; the product will represent the number of cubic inches of metal in the rim per H. P.; and this number divided by 1738, will give the number of cubic feet of metal, which multiplied by 450, (the weight in lb. of a cubic foot of cast iron,) will give the weight of the rim in lb. per H. P.

Therefore when $V^3 =$ cube of velocity of rim of fly-wheel in feet per second, $\pi =$ circumference of ditto in feet, we shall find

Formula 2.

$\frac{21300}{V^3} \times 12\pi$
1728 450 = weight of rim in lb. per H. P., and by reducing the constant numbers to a simple denominator, we shall obtain,

Formula 3.

$\frac{66562.5}{V^3} \pi =$ weight of the rim per H. P. in lb. For corn mills, this constant number would be reduced to 53250, and formula 3 would be $\frac{46593.8}{V^3} \pi =$ weight of the rim in lb. per H. P.

Rule 3. To find the weight in lb. of the rim of a fly-wheel, its velocity in feet per second, and circumference in feet, being given by Rule 1st.

Divide the constant number 66562.5 by the cube of the velocity of the rim of the fly-wheel in feet per second, and multiply the quotient by the circumference of the rim in feet, measured in the middle of its breadth, the product will be the weight of the rim in lb. per H. P.

Example. What should be the weight in lb. per H. P. of the rim of a fly-wheel of a 20 H. E., the circumference of the rim being 60 feet, and its speed 21.3 feet per second, (the stroke of the engine being 60 inches)?

$$\text{when } V = 21.3$$

$$V^3 = 9663.597$$

$$\pi = 60$$

$$\text{then } \frac{66562.5}{V^3} \pi = \frac{66562.5}{9663.597} \times 60 = 413.22 = \text{lb. weight of rim per H. P.}$$

By the rule to find the area, the cross section of the rim of the fly-wheel per H. P. would be $2.2 \times 20 = 44$ square inches, and

By the rule to find the weight, it is shown that the weight of the rim of the fly-wheel of a 20 H. E., would be $413.22 \times 20 = 8264$ lb.

In formula No. 3, π is the product of the length of stroke in feet, multiplied by $3.82 \times 3.1416 = 12$, so that by multiplying the constant number 66562.5 by 12, we shall obtain a new constant number 798750, which will admit of the following construction.

Formula 4.

$$\frac{798750}{V^3} S = \text{lb. weight of the rim per H. P.}$$

In formula 4, $S =$ the length of stroke in feet, this formula gives Rule 4. To find the weight of the rim of the fly-wheel in lb. per H. P., the length of stroke of the engine, and the velocity of the rim of the fly-wheel, being determined by Rule 1.

Divide the constant number 798750 by the cube of the velocity of the middle of the rim of the fly-wheel in feet per second, and multiply the quotient by the length of the stroke in feet, the product will be the proper weight of the rim in lb. per H. P.

Example. What should be the weight in lb. per H. P. of the rim of the fly-wheel of a 20 H. E., the speed of the middle of the rim being 21.3 feet per second, and the length of the stroke 5 feet (see column 2 and 7 of table A)?

$$\text{when } V = 21.3$$

$$V^3 = 9663.597$$

$$S = 5$$

$$\text{then } \frac{798750}{V^3} S = \frac{798750}{9663.597} 5 = 413.25 = \text{lb. weight of rim per H. P.}$$

giving the same result as obtained by formula 3.

For corn mills, &c. the constant number 798750, will be reduced to 559125, so that for such purposes the formula would be

$$\frac{559125}{V^3} S = \text{lb. weight of rim per H. P.}$$

The following table has been constructed according to the foregoing rules, and column 7 has been added for formula 5.

TABLE B.

H.P.	V^3	Area of the cross section of the rim per H. P. = $\frac{21300}{V^3} = a$.	Total area of ditto $a \times \text{H. P.}$	Weight of the rim per H. P. = $\frac{798750}{V^3} S$	Total weight of the rim	Relative load on piston per H. P. that of a 20 H. E. being one represented by $\frac{213}{W} = P$.
		sq. in.	sq. in.	lb.	lb.

90	729000	1.25	112.87	392.08	35287	0.828
100	1000000	1.21	121.11	393.81	39381	0.819

The precedent Rules 2, 3, and 4, will suffice when the proportions laid down by Rule 1 are adopted, but will not answer for general purposes; I have given them because, having for several years adhered to the length of stroke, and other dimensions shown in Table A, these rules have answered perfectly so far as the regulation of the motion of the engine itself is concerned, when exerting her full power.

The following Rules 5, 6, and 7, may be employed in all cases for the same purpose, let the stroke of the engine, the diameter and speed of the wheel be what they may.

Rule 5. To find the weight in lb. per H. P. of the rim of the fly-wheel, the length of stroke, the mean diameter, and speed of the

rim of the wheel, and the relative load per H. P. on the piston, (the load of a 20 H. E. being 1,) having been given.

Divide the constant number 37500 by the square of the mean velocity of the rim of the fly-wheel in feet per second, and multiply the quotient by the product of the length of stroke in feet, multiplied by the tabular number P (see col. 7, table B.), (P representing the relative effective load per H. P. on the piston, that of a 20 H. E. being 1,) the last product will be the weight of the rim in lb. per H. P.

Example 1. What will be the weight of the rim of the fly-wheel of a 10 H. E., when the length of the stroke is 4 feet, the diameter of the wheel in the middle of the rim 12 feet, and intended to make 48½ revolutions per minute?

$$\begin{aligned} \text{when } V^2 &= 928.4 \\ P &= 1.196 \text{ (see col. 7, table B.)} \\ S &= 4 \end{aligned}$$

Formula 5.

$$\frac{37500}{V^2} P S = \text{weight of rim in lb. per H.P.}$$

$$\text{therefore } \frac{37500}{928.4} 4.784 = 193.2 = \text{weight of rim in lb. per H.P.}$$

Formula 5 is thus composed :

$$\begin{aligned} \frac{10^2 \times 10}{V^2} P 12 S \\ \frac{144}{144} 450 = \frac{1000}{V^2} P S \frac{12}{144} 450 = \frac{1000}{V^2} P 37.5 S = \\ \frac{37500}{V^2} P S = \text{weight of rim in lb. per H.P.} \end{aligned}$$

Example 2. What will be the weight of the rim of the fly-wheel of a 10 H. E., its diameter in the middle of the rim being 12.733 feet, and making 26.7 turns per minute, the stroke being 3½ feet.

Observation; this example corresponds with the proportion given by Rule 1, as shown in the precedent table A.

$$\begin{aligned} \text{then } V^2 &= 316.84 \\ P &= 1.196 \text{ (see col. 7, table B)} \\ S &= 3\frac{1}{2} \end{aligned}$$

$$\text{therefore } \frac{37500}{V^2} P S = \frac{37500}{316.84} 3.986 = 472 = \text{weight of rim in lb. per H.P.}$$

For corn mills the constant number 37500 will be reduced to

$$\begin{aligned} \frac{10^2 \times 7}{V^2} P 12 S \\ \frac{144}{144} 450 = \frac{700}{V^2} P 37.5 S = \frac{26250}{V^2} P S = \text{weight of rim in lb. per H.P.} \end{aligned}$$

Rule 5, requires a series of tabular numbers, representing the relative effective load per H. P. on the piston, the load per H. P. on a 20 H. E. piston being considered as unity—this relative load varies inversely as the speed of the piston, and will be obtained (considering the speed of the piston of the 20 H. E., viz. 213 feet per minute as the standard speed,) by dividing 213 by the effective speed of the piston of the engine to be calculated; the quotient will be the relative value P required: column 7 of table B has been calculated so as to simplify the operation.

Admitting 213 to be generally allowed for the speed of the piston of a 20 H. E. in feet per minute, the calculation may be still further simplified, because a new constant number can be obtained by multiplying the constant number 37500 (given in formula 5) by 213, which would create

Formula 6.

$$\frac{37500}{V^2} S \frac{213}{W} = \frac{37500 \times 213}{V^2 W} S = \frac{7987500}{V^2 W} S = \text{weight of the rim in lb. per H.P.}$$

when V^2 = square of the velocity of the rim in feet per second.

W = speed of the piston in feet per minute of the engine to be calculated.

S = length of the stroke in feet of the engine to be calculated, which gives us,

Rule 6. To determine the weight in lb. per H. P. of the rim of a

fly-wheel, its speed in feet per second, the speed of the piston in feet per minute, and the length of stroke in feet being given.

Divide the constant number 7,987,500 by the product of the square of the velocity in feet per second, of the rim of the fly-wheel, multiplied by the speed of the piston in feet per minute, and the quotient multiplied by the length of the stroke in feet, will give the weight in lb. per H. P., of the rim of the fly-wheel.

Example. What will be the weight in lb. per H. P. of the rim of a fly-wheel of a 10 H. E., its diameter in the middle of the rim being 12.733 feet, and making 26.7 revolutions per minute, the length of stroke being 3½ feet?

$$\text{then } V^2 = 316.84$$

$$W = 178$$

$$S = 3\frac{1}{2}$$

$$\text{therefore } \frac{7,987,500}{V^2 W} S = \frac{7,987,500}{56,397.52} 3\frac{1}{2} = 472 = \text{weight of rim in lb. per H.P.}$$

For corn mills, &c. the formula would stand thus:

$$\frac{5,591,250}{V^2 W} S = \text{weight of the rim in lb. per H.P.}$$

the constant number 7,987,500, being reduced to 5,591,250.

To avoid misunderstanding it may be proper to repeat in this place, that Rules 2, 3, and 4, are applicable only when the length of the stroke and diameter of the rim of the fly-wheel, are made to correspond with columns 2 and 5 of table A, according to Rule 1, and when the fly-wheel makes the same number of revolutions as the crank; whereas the Rules 5 and 6 may be made use of on all occasions, be the length of stroke, diameter of the wheel and its speed what they may.

It is occasionally desirable to make use of a fly-wheel, that has not been expressly made for the engine to which it is intended to apply it, and it is then requisite to determine the speed at which the rim should travel to produce the usual effect on the motion of the engine; the following rule will determine that speed; the weight of the rim in lb., and the circumference of the rim in feet being given.

Rule 7. 1st. Divide the total weight of the rim in lb. by the number of H.P. of the engine, the quotient will be the weight of the rim in lb. per H. P., divide this weight per H. P. by the length of stroke of the engine in feet, and reserve the quotient for a divisor.

2nd. Divide the constant number 7,987,500, by the divisor found above, and divide the quotient by the speed of the piston in feet per minute, which will give the square of the velocity of the rim of the fly-wheel in feet per second, and extract the square root thereof for the velocity of the rim in feet per second.

3rd. Divide the velocity of the rim in feet per second by the mean circumference of the rim in feet, multiply the quotient by 60, and the product will be the number of revolutions the fly-wheel should make per minute.

This rule gives

Formula 7.

$$\sqrt{7,987,500 \div \left(\frac{\text{total weight of rim in lb.}}{\text{H.P.}} \div \text{length of stroke in ft.} \right)}$$

speed of piston in feet per minute

V = velocity of the rim of the fly-wheel in feet per second.

and $\frac{V}{\text{circumference of rim in feet}} \times 60$ = number of revolutions of wheel per minute, or

Formula 8.

$$\sqrt{7,987,500 \div \left(\frac{\text{total weight of rim in lb.}}{\text{H.P.} \times \text{stroke in feet}} \times \text{speed of piston in feet per minute} \right)} = V, \text{ and } \frac{60 V}{\text{circumference in feet}} = \text{number of revolutions of wheel per minute.}$$

Example. If a fly-wheel 15 feet in diameter, measured in the middle of the rim, and weighing (the rim only) 5000 lb., is to be applied to a 20 H. E., what number of turns should this wheel make per minute, the length of stroke of the engine being 5 feet, and the speed of the piston 213 feet per minute?

Length of stroke of engine in feet = 5.
 Speed of the piston in feet per minute = 213.
 Total weight of rim in lb. = 5000.
 Mean circumference of the rim in feet = 47.1

Then by formula 8.

$\sqrt{7,987,500 \div \left(\frac{5000}{20 \times 5} \times 213 \right)} = 27.4 = \text{speed of the rim in feet per second, and } \frac{27.4 \times 60}{47.1} = 34.90 = \text{nearly 35 revolutions per minute.}$

For corn-mills, &c., this formula would only vary by reducing the constant number 7987500 as stated above to 5591250.

therefore $\sqrt{5591250 \div \left(\frac{5000}{20 \times 5} \times 213 \right)} = 22.9 = \text{speed of rim in feet per second, and } \frac{22.9 \times 60}{47.1} = 29 \text{ revolutions per minute.}$

That is to say, that for machinery requiring regularity, the fly-wheel applied to a 20 H. E. should make 35 revolutions per minute, but if required to drive machinery for which regularity is not necessary, the same wheel need not make more than 29 revolutions per minute.

Formulas 7 and 8 are obtained by reversing formula 6.

London, October 11th, 1842.

H. H. EDWARDS.

NOTES ON STEAM NAVIGATION.

The management of the furnaces.—It is a common practice in steam vessels to pile the coal much too abundantly on the fire grate, the stratum of incandescent fuel is too thick, and the generation of carbonic oxide is the consequence, to the manifest diminution of calorific effect. The coals should be strewn upon the grate bars evenly and equally; the depth of the stratum should be about three inches, but this is a point dependent in a great measure upon the intensity of the draught; the stronger the draught the thicker should be the stratum of incandescent fuel. The bars should never exceed 7 feet in length, and should be as much less as possible; 5 feet is a good length, and not an uncommon length in the best boilers. It is impossible to fire long furnaces properly, especially in a sea way. We have known the length of the fire bars to be reduced from 8 ft. 6 in. to 5 ft. 6 in. with a great accession to the steam-producing powers of the boiler. The bars should always have a considerable inclination, both to facilitate the transmission of the fuel from their foremost to their aftermost extremity, and to diffuse the air more equably over their lower surface. The skill of firemen varies greatly, and due attention should be paid to their selection. A dead plate at the mouth of the furnace is a good thing, and combined with a slow combustion will obviate smoke and save fuel. These are the true secrets of combustion on chemical principles.

Boilers, wear and tear.—The wear of boilers is not unfrequently chiefly from the outside round the steam chest, from the dripping of water from the decks, in the ash-pits from the wetting of the ashes, and on the bottom of the boiler from the action of the bilge water. This last source of wear is now almost altogether obviated in some of the best steam vessels, by placing the boiler upon an efficient caulked platform, bedding it in putty—not an incorporated mass of lime and oil, but really sound substantial putty, such exactly as glaziers use. A coaming of timber is attached to this platform, encircling each boiler, and the interstices between the timber of the coaming and the iron of the boiler are filled in with roman cement, and sloped off on the upper side, so that no water can lie on the cement or coaming. It might be expected that these coamings would be disturbed by the expansion of the boiler when heated, but we find that the expansion is so inappreciable in practice as not to be productive of any visible derangement. The upper parts of boilers should be covered with felt

and sheet lead, soldered wherever there is a joining; the practice of covering boilers with felt and sheet lead is now almost universal among the best engineers.

Blow-off cocks are a perpetual source of annoyance if they be not well made at first. The metal of which they are composed should be hard and tough, without any lead in it. The plugs of the cocks, if made with too little taper, will be very apt to jam, and after having been ground a few times, will sink so far into the socket as to come in contact with the bottom, if there be one, and diminish materially the effective area of the water way. If the taper be too little on the other hand, a great strain will be thrown on the gland, which keeps the plug in its place, and if they give way it will be driven out with great force. This did occur in the Great Western, and the engineer was scalded to death.

The durability of brasses is dependent upon a variety of circumstances, but chiefly upon the quantity of rubbing surface and the quality of the metal. We have seen a brass of Boulton & Watt's which had worked for thirty years, and was at the end of that time in good preservation, whilst we have seen other brasses which, in the course of a couple of years, were quite worn out.

De omnibus rebus et quibusdam aliis.—Should the engineers be subject to the captains? In generals, YES—in particulars, NO. The Admiralty regulations in reference to engineers are just as preposterous as might be expected, inasmuch as the Admiralty is invariably a century behind the merchant service, but in their regulations respecting engineers, they have out-Admiraltied themselves and earned a title to a squabash with our tomahawk, with which we may probably honour them on an early occasion. The Admiralty desires to have young men of education as engineers, and yet with Admiralty consistency rates the engineer *beneath* the ship's carpenter—and what engineer of talent and education would place himself in so abject a situation, or submit to be snubbed and brow-beaten by every whiffing lieutenant or embryo midshipman who does not know the garboard streak from the log line? As to your amateur mechanics, we always shun them as carefully as we would do a rabid dog; their bite is dangerous, and their bark—why that of Cerberus was heavenly music to it. We have never recovered from the alarm we once experienced from the spectacle of one of these *cognescenti* with blackened fustians and white kid gloves, crawling daily, for the space of a whole week, through the labyrinths of an oily steam engine, to vindicate his title to engineering proficiency. We bethought ourselves of Nebuchadnezzar, and betook ourselves out of reach of the saliva. When we take upon ourselves the administration of the Admiralty, which, between this and 1942, we may perhaps be prevailed upon to do, our first operation will be to get a leviathan besom constructed to sweep away all such incurables preparatory to placing engineers in their proper position.

Ventilation is a thing greatly neglected in steam vessels, although so many facilities exist for establishing an effectual system. Every vessel should be fitted with one or more fans, or Day's patent Archimedean Screw ventilator, worked by the engine for exhausting the air from the different cabins, gratings being left above the doors and in other suitable places for the admission of fresh air from without. The same mechanism might be made to draw air from the holds and other parts of the ship, so that any bad smell from bilge water, &c. would be entirely obviated. In tropical climates, in particular, no steam vessel of any considerable size ought to be unprovided with a ventilating apparatus.

The rolling of steam vessels in a sea way gives a lateral impulse to several parts of the machinery, which it is often not well calculated to resist, without a considerable jolting. Thus the side levers will, when the vessel rolls heavily, slip in and out upon the main centres, and the shafts will move endways. It is true there are collars to prevent this, and in new engines no great movement of this kind can take place; but the collars are in most cases much too small—they are deficient in rubbing surface, and they consequently wear, in a short time, considerably into the brass, leaving a lateral play upon the journal which admits of no adjustment. To obviate this evil, Messrs.

Maudslays & Co. are in the habit of making their journals with very large fillets in the corners, so as, in fact, to make each end of the journal a short frustrum of a cone. This has the desired effect, but occasions a wasteful expenditure of the oil. Mr. Robert Napier makes his cranks to bear against the flanges of his brasses. This plan obviates the rapid wear, but still leaves any wear that has taken place unsusceptible of re-adjustment. The best plan, it appears to us, would be to make each journal bulge out in the middle, so as to constitute, in fact, a portion of a spheroid, and recess each brass correspondingly. The act of tightening the top screws of the journal would then have the effect of preventing the shafts from moving on end, as well as of preventing them from moving up and down. The outer bearing of the paddle shaft should be always so made as to admit of easy adjustment. A common plumber block with the top constructed for holding tallow, placed upon a good stout carriage bolted to the fore and aft bearers, is, in our judgment, the best arrangement. The plumber block bolts should be so made that they may be dropped down to admit a piece of plate iron between the sole and the carriage at any time the shafts may require re-adjustment. A brass in the upper part of the plumber block at the outer end of the shaft is unnecessary, as there is no upward strain, and the cover bolts should be merely sufficient for holding it on in a sea way. This journal always wears forwards as well as downwards, and the brass should be so made as to admit of the aftermost side being turned before. The sides of the brass should also be thicker than in journals where this action does not exist.

Piston Rods.—The best mode of attaching the piston rod to the cross head is by means of a cone and cutter and gib, and a screw above the cone; this cone should have considerable taper both to obviate any injurious expanding action which a cone of little taper would occasion, and to facilitate the disengagement of the rod when it requires to be taken out. Some of Boulton and Watt's cross heads are made close over the piston rod, except that a little hole is left in the top to admit the introduction of a drift to start the piston rod when it requires to be disengaged. This we think is a very objectionable plan, and we have known it in practice to be productive of the most serious inconvenience; for a small drift will not start a rod on which the taper is not considerable, and which is rusted into its place. The drift may indeed be assisted by a cutter driven into the cutter-hole, and so contrived as to force the rod down instead of keeping it up; but even with this aid we have known the largest drift that could be introduced through the top hole to be quite ineffectual in starting the rod. It is a bad practice too to make the upper part of the rod that fits in the cross head eye parallel; a blow or two upon this parallel part will stand and swell it so as to rivet the rod into the socket.

Iron Ships have been much cried up of late by iron ship builders. We admit their claims to favourable consideration, but at the same time maintain that they are attended by many serious disadvantages. In the first place the accumulation of sea weeds and barnacles is a formidable objection. We have seen indeed a scheme of a scraper for removing these accumulations whilst the vessel was under weigh, but it is in our mind puerile and impracticable. Again, the iron of which vessels is composed has been found to become brittle in the course of years, so that although tough at first, it will in the course of time star like glass when struck by a hard and sharp body. The action appears analagous to that which takes place in railway axles. Mr. Nasmyth, indeed, has shown that railway axles are rendered brittle by cold hammering, and may be toughened again by annealing; but he has not shown that axles are not rendered brittle also by continued wear, or that this species of brittleness admits of the same remedy.

Bilge Pipes are best of lead, both because lead resists the action of the bilge water better than any other metal and because it is much cheaper than copper. But the blow off pipes should never be of lead; lead blow off pipes bulge and burst from the continued heat and fragrance to which they are subjected. We find that Mr. P. Taylor at the Institution of Civil Engineers, a short time ago recommended all the pipes exposed to the action of the bilge water in any measure

to be of lead, and his recommendation was allowed to pass without comment. We therefore think it expedient to say that we altogether differ from Mr. Taylor in this particular. Neither the blow off or deck pump pipes should ever be of lead though they are always more or less exposed to the action of the bilge water. No engineer in this country ever thinks of making blow off deck pump, or injection, pipes of anything but copper.

Waste Steam Pipe should be as high as the funnel, especially if situated before the funnel. When the waste steam pipe is shorter than the funnel, the action of the steam on the iron of the funnel rapidly oxidizes it and speedily makes the funnel very thin in that part of the ascent to the mouth of the waste steam pipe. When the pipe is made as taunt as the funnel the steam is carried clear of the funnel altogether.

Stop valves between the boilers should be permitted always to act of their own accord, and should never be opened and kept open by drawing up the spindle and keeping it up. Unless the stop valves be allowed to act spontaneously like the safety valves, they will soon become so fixed by corrosion that they cannot be shut at all, and are consequently of no avail. If the increased pressure incident to the weight of the valve be objected to, that weight may easily be balanced by a weight and lever attached to the spindle, where it emerges from the stuffing box of the valve box cover.

Rudder. It is a judicious practice to make the rudder rather shorter than is requisite to reach the keel—the rudder will thus be unaffected if the vessel takes the ground. The keel should always project a little beyond the rudder joint so as to prevent warps or ropes of any kind from catching in the joint as the vessel passes over them. The rule joint is the best species of joint for a steam packet rudder, and by far the neatest: the rudder head should be round and should fit accurately in the rudder trunk, which of course should be a cylinder.

Paddle box boats of Capt. Smith are we think inconvenient—unsightly and ineligible. It would be greatly preferable to have a dozen boats stowed inside one another like the nests of pill boxes of the apothecary. In a heavy sea the paddle box boats could not be raised without great difficulty, and when raised could scarcely be approached. Their proximity to the paddle when launched is dangerous, and the waves would fly up through the paddle box in a sea way with great force, and cut off all communication between the boat and the ship. We regret that Capt. Smith has not found a better vehicle for his ingenuity than this cumbrous, ineffectual and unsailor-like contrivance.

CANDIDUS'S NOTE-BOOK. FASCICULUS XLII.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. Mr. G. R. Lewis' notions in regard to "intelligence of design" and symbolical expression in ecclesiastical architecture, are too transcendental, not to say, whimsical, to be adopted by our modern church builders, and perhaps it is well that such is the case, since the fanciful mysticism which he recommends might lead to conceits that had better be avoided, ambiguous at the best, and occasionally susceptible of very sinister interpretations. A very great deal of symbolical meaning, whether intended or not, shows itself, for instance, in the design of Bernini's celebrated bronze baldachino in St. Peter's, although critics who look no further than their noses have never detected it. Many of them have reproached the artist for his bad taste in making the shafts of the columns *twisted*, and as far as mere external form goes, they are right; but then they quite overlook the mystic meaning couched under that form. Those columns wind themselves in folds like so many huge serpents, rearing their heads aloft, and thereby typify, in the most expressive manner, both the *serpent-like*

subtlety and the *crooked policy* of the Romish church. This instance, however, is not even alluded to by Mr. Lewis; so far from giving modern architects and artists credit for any ideas half so ingenious, he complains that they have not only abandoned all "intelligence of design," but more or less *paganized* our churches, and made them compounds of "classical heathenism." In his horror of heathenism he is, in fact, a second Welby Pugin, and perhaps the more consistent writer of the two. Yes, he is consistent and he is honest, which, as the world goes, are two especially rare merits, although his honesty is not of a kind at all likely to recommend him, because he blurts out sundry highly disagreeable remarks against many of our architectural idols—"time-hallowed" and "book-hallowed" structures, for which our implicit and uninquiring admiration is claimed as matter of course, or rather as matter of faith. So far from sparing the "wonderful" Sir Christopher Wren, Mr. Lewis treats that "illustrious architect" very cavalierly indeed, calling him, in all but direct terms, an ignoramus and a bungler; for which he will, no doubt, now get a sound drubbing from Professor Cockerell. But it is not merely particular buildings or architects that Mr. Lewis attacks, he goes much further, and loudly reprobates the whole of the present system of our architectural doctrine and taste, urging us to "shake off the trumpery trammels that have been placed upon us by unnatural education"! This is, indeed, startling, and most awfully so! What is, in such case, to become of such venerable authorities as the great Vitruvius and the great Palladio?—what of the Professors who look up to them for inspiration? The former would be damned, the others "unfrocked." Neither is this all; for Mr. Lewis is such an ultra-reformer, and so obstinately consistent that he is not disposed to tolerate heathenism in our literary education. The man is so blind that he does not perceive how highly proper it is that our youth should be early initiated into the mysteries of heathen mythology, become familiar with the lewd amours of Jupiter and the other Olympian scoundrels; or with revolting and unutterable impurities in the classic poets, which elder school-boys translate for the edification of their juniors. He is for tolerating nothing of the kind; on the contrary, he would fain cleanse the Augean stable of classical art, and ruthlessly despoil our galleries of their most valued treasures,—even of such innocent subjects as combats between Centaurs and Lapithæ, and Greeks and Amazons. With reference to these, "Who would suppose," he asks, "that such disgraceful acts should be considered as fit and proper subjects of study for our youth in this Christian country? Is the act of one man chopping down another worthy of imitation, or the monstrous brute in human form running his sword through the body of an Amazon an idea sufficiently refined to place before our youth—for their improvement? Perhaps we shall be told, that as they have been considered by committees of art to be most exalted works, that they are perfection, and therefore placed in the Museum and National Gallery, that the public may learn how to admire acts of cruelty, and our youth to become skilled in murderous and artificial attitudes, that they may be enabled to produce such sublime and beautiful works as will tend to the enlightenment of the irreligious and immoral. Such are some of the absurdities that are established for the improvement of the rising generation. Need we wonder, then, at our inability to produce original designs? Can it be otherwise? Certainly it will not be while Pagan, Greek, and Roman works of art are to be considered the foundation on which our youth are to be instructed. No style should be held up for imitation, however sublime it may be. Every work of art should be purely an invention; and whether it is to be a church or a picture, the designs for either should arise out of the subject." This will serve as a specimen, though but a mere specimen, of Mr. Lewis' doctrine—singular, perhaps offensive, nor the less so because it is impossible to gainsay it without touching upon very dangerous ground, and attempting formally to defend a very great deal that our convenient hypocrisy now winks at.

II. The "Institute," it may be presumed, are very little aware what a dreadful architectural heretic they have admitted among them as one of their foreign members, in the person of Alexander Bruilov or Brinlov of St. Petersburg. In a letter of his dated from Naples,

April 21st, 1825, and published shortly afterwards in a Russian journal, he expresses himself not a little contemptuously in regard to the manner in which architects who go thither for study and improvement occupy themselves in Italy. "It may appear," he says, "exceedingly strange and even absurd to many—more especially to those *fanatics in architecture* who have no notion of, nor care for any thing beyond their compasses and rule—that an architect should employ himself with painting brushes and palette; but without attempting to justify myself, or to point out what does and what does not belong to an architect's studies, I will only say that the more varied they are by being extended to other branches of art, the more likely are architects to become *artists*, and to give evidence of being such, in their immediate profession. Therefore, although I am very far from reckoning myself among those who are gifted with a variety of talents, I do not scruple to take up with other pursuits besides those which more directly belong to me as an architect. Is it not far better, in fact, to occupy one's-self with what will improve one's taste and imagination, than to pore over a shapeless mass of stones and rubbish, idly conjecturing to what edifice they once belonged, or as idly pronouncing what such edifice originally was?—yet, after such fashion it is that many of those who visit Italy pursue their architectural studies. I do not, however, go so far as some do, and say that the architect can learn nothing in Italy that he might not equally well do at home, but I will say, that if, after wandering through the Vatican, and among the temples and other ruins of ancient Rome, an architect does not feel that he has caught something like inspiration from them—does not feel elevated by the idea that he also is called to be an artist—the only, at least the best thing he can do, is to fling away his compasses, and betake himself to any other calling." How far Bruilov himself deserves to rank as an artist in his profession, I am unable to say, nor does Nagler afford me any assistance, for he merely mentions a single work of his, viz., the new Observatory at St. Petersburg; it may therefore be a welcome though small addition to that meagre piece of information to state that among other buildings by him are the following ones: The Mikhailovsky Theatre, opened in 1838; the Lutheran Church, St. Petersburg (Gothic); several of the apartments in the new Winter Palace; and a Gothic Church at Pargalova.

III. A writer upon architectural subjects in the *Spectator*, who, upon the whole, exhibits both cleverness and smartness, is occasionally sadly at fault, and most assuredly so when he expresses somewhat like surprise that bow windows should not be thrown out "in front of almost every London dwelling." No doubt a bow window is very agreeable in a room, but then it is so only so long as it is a *privilege*. Were every house in a street to have such windows, instead of being able "to see up and down the street," people would only see that their neighbour's bows on each side of them were very great bores—positive nuisances, not only as intercepting their prospect, but destroying their privacy, rendering it impossible for them to pass to and fro that part of the room without being subjected to the impertinent gaze of the "people at the next door." A single bow-fronted house in a spacious street or square may be a luxury to the fortunate occupier of it; neither would there be much inconvenience attending the making a bow to every house, provided every house had a frontage equal to that of the National Gallery; but for our scanty and narrow-fronted London houses, they are out of the question. A series of bows would cut up the side of a street into a series of awkward projections, separated from each other only by narrow strips of flat wall. So far, therefore, our street architecture would not be at all improved. In fact, unless a "bow" be of such extent as to be, not a mere feature in it, but a portion of the entire front, it would be exceedingly difficult to make any thing tolerable of it externally, in either the Grecian or Italian style. After all, too, the sitting at a window merely to look up and down the street is very melancholy work.

A congress of architects at Leipzig—the first assemblage of artists ever held in Germany—met on the 14th Sept., to the number of 547, nine of whom were Englishmen. The town of Bumberg, in Bavaria, has been fixed on as the place of their meeting next year.

ON THE DEVELOPMENT OF THE SEMI-ARCH WITH THE FUTURE ADVANCEMENT OF ARCHITECTURAL ART.

By ROBERT CAREY LONG, Architect, Baltimore, Maryland.

In an article which appeared in the Franklin Journal some months back, we attempted to show that the charge of degeneracy was laid against modern architecture, and that this charge could be sustained, inasmuch as in architecture the law of imitation was substituted for that of originalities, the copying of the external forms of the architectural remains of the past for living principles of composition, so that now instead of an architectural work being an organized body, where the external features were the natural result of its internal arrangements and uses, it was, in fact, a mere mass, the parts of which were held together by the arbitrary laws of external form.

We took occasion to say, that the merely changing the style, or fashion of architecture, would in no way effect its regeneration, for, as long as we follow the law of imitation, it makes little difference whether Grecian or Gothic be our model—and yet, we cannot but think the art capable of being roused from its present prostrate condition. For although its forms lie shattered and almost in decay, yet there are living principles of construction from which these very forms have originated, which, if properly understood, and infused into these apparently dead elements, would effect a reorganization, and architecture would once more exist, in newness of life, and perfectness of beauty.

In this all architectural critics agree. No one who knows anything of the subject but admits, that, ever since the downfall of the gothic, architectural art has been in an unprecedented state of degeneracy, that not only has no new architectural style been formed, but not a single element of construction, wall, column, arch or buttress has been developed beyond the condition in which the 15th century left it.

Deplorable as this condition is, it is not yet hopeless. We may even discern in the fact of the growing dissatisfaction manifested towards almost all the modern specimens of architectural design, the dawn of a better era. When the architect looks back into the past, and reflects upon the progress of architecture in all time, observes the sublimity of its forms, and the stately solemnity of its measured footsteps among the Egyptians—sees its aspect of grace, proportion, delicacy, and consummate beauty among the Greeks—notices, among the Romans, the change that takes place in its forms and expressions, its massive piers, its overhanging domes, the triumphal arches, and the fantastic and luxuriant character of its decorations, mingling like the stern battle cry, and the shouts of victory and dominion with the dulcet notes of love and revelry—when he observes also, how this architectural system is broken up before its discordant elements have formed themselves into a consistent whole, now, while a constant struggle is still going on amongst them, the Roman empire falls, and from its fragments new nations arise, and a new architecture comes forth, built as it were upon the wrecks of the *whole of the past*, rising heavenward, and like an organ symphony, combining majesty with grace, solemnity with fancy, with a dim mysterious connecting melody running through all its changes. When he again beholds how even this form of art endureth not, but changes, and as the master spirit abandons the keys of the instrument, (to continue the simile), sees fancy overpowering dignity, harmony becoming wild and rapid, till at length the connecting melody is lost and universal discord reigns supreme; when the architect views all this, can he help feeling that his individual genius can do but little in his art, that the *spirit of the age* must be manifested in its architecture, and that he must be inevitably overruled in his efforts towards a regeneration of the art, unless the community can be made to understand and feel this state of degeneracy, so as to call for and second any movement that shall be made towards the formation of a style of architecture *peculiar*, characteristic of the age, suited to its wants, its desires, its demands.

Since it is the sincere wish of every lover of architecture to see this art leave the trammels in which, at present, it seems bound hand and foot, and take once more that rank among the arts of design which it held among the Egyptians, the Greeks, and the architects of

the early Christian church, it becomes all such to look around and endeavour to discover some means of effectuating this important result.

It is granted by all who know anything of the subject, that architecture is not now even what it was during the development of any particular style, that the law of *imitation* instead of *originality* having become the rule of design, *precedent* must be quoted for every individual feature, in short, that the architect is bound down to a *pattern*—a *style*; and that the best he is expected to do is to produce something similar to what has been produced, only sufficiently common and cheap to be built at the present day, all departures from this pattern being considered necessary or accidental faults.

None can feel so deeply this degraded state of this art as the professor of it, when called upon for a design for a building; to be consecrated to the service of his country, or of his religion. Wherefore, he says within himself, should I study the principles of architectural construction? Wherefore should I know that no beauty can be produced without truth of design? Wherefore should I feel all this love of the beautiful in my art, this perception of its capacity for perpetual rejuvenescence and perfection, if I am still obliged to grope on and produce something so far, so very far, behind all that has been done in the days that are gone?

Yet what can be done? Can the architect be before the age in which he lives? Can he do anything to counteract the law, that the peculiar genius of every people must be impressed on their architectural works? How little evidence of individual genius is ever presented in architecture! Look at all the great works of the past; no feature in any style but must have had a beginning, and that too in the mind of man, and yet style after style has arisen and departed, without bearing witness to the genius, or perpetuating the name of the individual minds producing it.

Though these reflections are chilling to the heart of one who is an ambitious struggler after perfection in his art, they should not yet paralyze all endeavour after progress, for, although the architect cannot be in advance of his age, he can at least diligently observe and faithfully interpret its tendencies. To that which in the community already exists as a feeling, he can give a body in thought, and make visible to the senses in form.

Now who has not observed in this day not only a growing dissatisfaction towards all the productions of modern architecture, but also a spirit of hope, a desire after progression and improvement. Let the architect make his building Greek in all its parts and proportions, objection at once is made that it wants originality, or that it is not equal in ornament or richness to the model from which it is copied. If he should choose the Gothic as the mould in which his ideas are to be cast, his production is laid side by side with a magnificent old cathedral, on whose construction and decoration were lavished the wealth of a monarch, the piety of a whole people, the genius of almost inspired artists, and in the consummation and perfecting of which, the most powerful hierarchy that the world ever knew spent century after century. What comparison can be drawn between the meagre production of a single brain, and the manifestations of the maturely developed combination of such elements of greatness? But let the architect be so unfortunate as to design a building in what is called the Roman style, that absurd conglomeration of arches, pediments, columns, piers and pedestals, domes and porticos, and, although he may cite a precedent for every abomination he may commit, though he may by line and rule perpetrate the greatest violations of every principle of truth and beauty, and cry out to every objection raised, that his design is *Roman* and must be judged by Roman law, the day is past that the declaration can avail him anything; he too must be brought before the bar of universal criticism, and be made to answer before the tribunal of taste.

Now the question is, where is improvement to commence, from what point must progression take place? Can the architect invent a new style? What architect ever has done it? Can he even improve on what is already invented? Let him try to alter one jot or tittle the law of Grecian proportion, and witness what a mis-shapen abortion is the result. Let him add but *one* more to the number of the

three orders, and order is changed into confusion. Let him attempt to combine the purity and perfectness of the Grecian features of design, with those of any other style of architecture, and he will be made at once to acknowledge that the *beauty* of Greek design depends upon its *purity*, the perfect consistency of all its parts, and their unity of expression. A Grecian building is *one thought*, one full harmony: to catch its expression, it must be unmodulated, unaltered, unalterable. To effectuate this, the architect cannot dare to depart from the known proportions used by the Greeks themselves, until he has discovered the law from which those proportions originate. Until he makes this discovery, the Greek models he must continue to copy, line for line, he must measure every moulding with the most slavish accuracy. Let his design differ in the least particular, the charge of ignorance or presumption may be raised at once against him, and that too, his own good sense will acknowledge with perfect justice.

What too can the modern architect do with the Gothic? Can he improve upon this style as manifested in some of the old cathedrals of the middle ages? As well might he attempt to revive the feudal tenure, to raise another crusade, or re-establish the institution of chivalry. He can do little in the Gothic except to study the wonderful science of its construction, the exquisite beauty and *melody* of its details, the picturesque effect of its arrangements, and beneath the vault of its overhanging roof, or looking round at the clustered columns, the glowing windows, and the saintly shrines, bow down in mute wonder at the genius that could project, and the science and skill that could execute such a miracle of beauty.

The utmost perfection to which an architect can now attain in the Gothic style falls immeasurably short of the excellence of the olden time, neither can we ever expect to see the day in which such structures as the cathedrals, castles and mansions of the middle ages shall be needed. Modern gothic, or the manner in which Gothic architecture has been latterly revived and applied to the uses of modern times, has brought upon the profession such merited derision and contempt, that we need not fear an universal adoption of this style at the present day, however much it has been denuded and brought down to a *bare-bone* state, to suit the economical display-loving spirit of the age. Still the architect who wishes to bring about a new era in architecture must study the remains of this last great style, in order to see manifested in it, those universal principles of truth which are the tests of the excellence of all styles, principles which are disconnected with that idiosyncrasy which constitutes a style, principles by which the architect must be governed in the formation of any new one.

Since, then, Grecian and Gothic architecture as styles exist, in an unimprovable condition, so that perfection in them depends upon accuracy in copying existing forms and details, which copying can never raise architecture from its present state of degeneracy, seeing that this same copying has been tried for 300 years, the architect must now take some other method of resuscitating it. He must infuse some principle of organization into the very elements of its being, the ultimate atoms (if we may so express it), of architecture must be transfused into some medium where they may arrange themselves according to some law of affinity which must exist among them.

Among the different modes of architecture that are at present in use, it appears to us, that there is but one in which an architect, to be great, must use the *principles of its construction only*, without adhering to the details of any model. This is what is called the Roman style, that which is distinguished by the use of the *semi-circular arch* and the *dome*. The people to whom the invention of these modes of building is generally attributed, were prevented, by many reasons, from forming them into an architectural style, notwithstanding the fact of their great capability of being so formed. Possessing little artistic genius themselves, the Romans had the good sense to reverence its manifestations among other nations. They acknowledged the supremacy of Grecian taste, and admitted the unrivalled excellence of Grecian architecture. The Greeks were then their teachers in this art, but unfortunately, at a period when the life and liberty of Grecian art was but a name; the consequence of all this was, that instead of

the Roman arch being used as a legitimate architectural feature, bearing the same relation in a building to the part it supports as a Grecian column does to its entablature, it was used as a mere element of construction, or as a fanciful form for an opening in a façade, while in that same façade were placed the horizontal lines of a Grecian entablature, with its own appropriate columns. Thus, two forms of support were used in the same building, to perform the same office, and an architectural pleonasm engendered, whose progeny exists even to this day. That Grecian columns and entablatures could not long preserve their character in such association was soon made evident. The Romans wanted to increase the height of their buildings beyond Grecian proportions, the use of the arch permitted them to build story upon story, and in so doing, every story was accommodated with its own string of entablature, and its own columns. When the story was too high and the space between the arches too small for the due proportion of a Grecian column, by the invention of pedestals, the columns were mounted upon stilts to stretch them out sufficiently, and we thus see Grecian architecture entirely passed away and nothing worthy of the name of a new style substituted in its place, where nevertheless an architecture could have risen, for the germ of a glorious architecture is there.

It seems to have been the peculiar fate of the semi-circular arch, in its different development as a constructive feature, to have failed entirely in creating a distinctive style of architecture, founded upon its use, and characterized by individual features, resulting from its use alone. Not only did this principle of construction fail of a perfect development among the Romans, by whom it was first, as far as we know, extensively used, but at a later period, when, in what is called the Norman style, it seems just arousing itself and coming forth with a freshness and vigor that shows the promise of a new and appropriate style, its progress, by some fatality, was cut short, and all the energy manifested in it turned into a new channel opened by the introduction of the pointed arch. Had this latter never been invented, and had the same genius which produced such a wonderful architecture from this modification of the arch brought its powers to bear upon the semi-circular form of construction, may we not with propriety believe that a style would have arisen out of this latter curve as magnificent and sublime as the Gothic, and when we look at what has been produced in this case, is there not something in the fact to tempt the aspiring architect to study out, and aid the more perfect development of the semi-circular arch.

A style of architecture in which the semi-circular arch shall be used may combine in perfect harmony with every element of construction which has been developed, in all ages past. It may call into use the wall, the column, and the buttress; column not necessarily Grecian, walls no longer Egyptian, buttresses not of necessity Gothic—a mode of architecture, which, while it may admit the utmost gorgeousness of ornament, expensiveness of material, solidity and durability of construction, with vastness of magnitude, may yet be beautiful in its simplicity, and by the manifest use of all its parts, be satisfactory to the mind which desires *sense*, with utility and unpretentiousness—a *unique* mode of architecture, suitable alike for the palace and the cottage, the church and the theatre, the villa and the home of the citizen, the light pavilion of pleasure, and the gloomy portal of a prison—in short an architecture which will take its character from the use to which it is applied, and which can be judged by no rules but those arising from common sense, perfected judgment, and refined taste.

In such a style the arch must have its own place in a building as *the support of the shelter*, and to the shelter, as its appropriate form, must be given the shape of the dome, so as to appear to have, and to have indeed, some relation to that on which it rests. A foundation too must be provided on which the supports shall stand, of some just proportion; the entrances and openings must all be arranged in symmetry with the whole; an architectural beau ideal, in fine, must be formed, for the realization of which we shall search Rome in vain.

In using thus the semi-circular arch, that is, in combining it with other elements of construction, it will be necessary that it should hold

the supremacy, and that these other elements should be made subservient there, the wall—the column—the buttress, all can be employed as accessories, and this latter with especial propriety, as having far more use to perform in a building in which the semi-circular arch is used than one in which the pointed arch prevails; for the form of the latter is such that it seems almost fully adapted to dispense with such assistance, and though we would not use Gothic-shaped buttresses and pinnacles with the semi-circular arch, yet why may we not readily use the thing itself, letting peculiar forms arise from its new association and adaptation?

A mode of architecture would thus be formed which would be capable of every variety of use, and which would give scope to the highest flights of genius and originality, borrowing even its decorations from no arbitrary model, but creating them out of the very necessities of the case—an architecture whose primitive form could be traced neither in wicker work, (according to Sir James Hall's theory of the Gothic,) nor in log huts, (according to the Vitruvian account of the Greek orders,) cotemporary tents, like the Chinese style, nor subterranean excavations, the supposed prototype of the Egyptian, but as essentially a creation of the art of building as when that art was best understood. Such an architecture the world has been on the eve of beholding twice, and yet it has never attained to the blessedness of seeing it accomplished; the early Christian before the Gothic style was formed, evincing, as we have just said, a decided tendency to the formation of a perfect style of architecture, on the semi-circular model, and the taste of the age, after the Gothic fell from its "high estate," the age of the reformation, seeking out again the Roman arch, but falling into the error of imitating Roman architecture, as it is called, the architecture of Palladio and others, with all its absurdities, which unfortunately it took for a model, instead of developing still further what previously had been attempted in the Norman style.

The formation of an architecture such as we have here imperfectly sketched out is the work of all succeeding ages, it is what this age is asking for, but without obtaining it, for false taste, the laws of *precedent*, the idea of orders and styles (which never prevailed during the formation of any real architecture) in fact the very reason which prevented the Romans from creating an architecture, out of the very principle of construction we have been considering, still prevail, and are preventing us from producing anything in this art which we can call our own.

The architect who shall be bold enough to commence the innovations necessary as preludes to such a state of art must stand in an imminent deadly breach. He cannot answer the question "In what style is your design?" He cannot call it Roman, for it must violate none of those principles of taste which they who have studied the architecture of all nations—the well-informed—know to be true; it is not Greek; it is not Gothic; it is not Egyptian. The sentence will be "away with it, we know not what it is!"

But should there be found men sufficiently unprejudiced to suffer such a style to be formed, one will arise admitting of all the excellence of Roman construction, Grecian beauty, Gothic grandeur, and Egyptian sublimity, with propriety of plan, purity of design, simplicity and utility in all its details; the days of small things shall have passed away, and *genius* will be no longer considered a supernumerary qualification in an architect.

Baltimore, Maryland,
Aug. 26, 1842.

MEMOIR OF THE LATE JOHN GOLDICUTT, ESQ., F.R.I.B.A., &c.

It is with deep regret that we have to announce the decease of John Goldicutt, Esq., architect, of Clarges Street, Piccadilly, who died on the 3rd of October, aged 49. His father was, for many years, the chief cashier and confidential clerk at the banking house of Herries, Farquhar & Co.; and observing in his son an early predilection for drawing, he placed him in the office of the late Mr. Hakewill, who executed considerable works at Rugby School, and built St. Peter's church, Pimlico. Mr. Goldicutt soon acquired considerable skill in drawing, and evinced a happy disposition for colours, a

most important branch in the education of the architect. He soon joined an association called the Architectural Students' Society, consisting of young men, who met every fortnight in order to make sketches from given subjects, and thus acquire a facility of design. He on two occasions was a competitor for the silver medal at the Royal Academy, and with this view measured and drew out the façades of the India House and the Mansion House in successive years, and was successful in carrying off the prize for the latter subject. Mr. Goldicutt throughout his life evinced the same ambition of distinction, and on all public occasions was sure to enter the lists in any competition with his professional brethren, which seemed to offer the prospect of a fair and honourable adjudication. After availing himself of the experience to be acquired in the office of Mr. Hakewill, Mr. Goldicutt was sent by his father abroad, and went first to Paris, where he entered the school of Monsieur Achille Leclère, a distinguished pupil of Monsieur Percier, whose reputation he sustained by the brilliant fruits of his studies as Pensioner of the French Academy at Rome. Mr. Goldicutt completed, under this master, his studies as a draughtsman, and regularly competed with his fellow students for the monthly prizes in the Académie des Beaux Arts. He then went to Rome, where he carried out his predilections for decorative architecture by making a rich collection of sketches from the most valuable fragments of the ancient monuments. His most remarkable work, while residing in this capital of the fine arts, was a splendid transverse section of St. Peter's church, which he most elaborately worked up, representing the splendours of that remarkable edifice, with all its sumptuous decoration of gold and colour, and splendid pictures by the first masters. This production, which is the happiest effort at drawing of the English school of architecture, excited so much admiration that he was prevailed upon to submit it to the inspection of the Pope, who presented him with a large gold medallion as a mark of his gracious approval. After an absence of 3 or 4 years, Mr. Goldicutt returned to England, and commenced his professional career of practice as an architect; and soon his refined taste, lively imagination, and facility of drawing, introduced him into considerable private practise, and he severally carried off prizes in competition for the Post Office, for the Lunatic Asylum, and other buildings. Mr. Goldicutt always entertained a most active and generous enthusiasm for his art, and was ever one of the foremost to join in any proposition which he thought would honour it and raise the profession in the estimation of the public. He was one of the original founders of the Royal Institute of British Architects, of which he was one of the first Honorary Secretaries; and in his own house originated the proposal of the Soane testimonial, in carrying out which he devoted much time. The whole arrangements of decorating Freemasons' Hall on the occasion of presenting Sir John Soane with the medal struck in his honour, devolved upon him; and the taste and skill with which he arranged the embellishments, excited the admiration of all present on that venerable night. Mr. Goldicutt was elected Member of the Academy of St. Luke's at Rome, and of the Academy of the Fine Arts at Naples. He was a competitor for the Nelson monument, and sent in a design consisting of a colossal figure of Nelson, standing on an immense globe, which reposed upon a pedestal in the centre of a large basin, which served as a fountain. The novelty of the design excited great attention at the time, but so little prepared is the public mind for any new conception at variance with its old established notions, that exception was taken to the daring project in many of the public criticisms of the day. But we cannot but concur with the remark of a distinguished amateur, who observed to us recently, that if such a design had been executed in Germany to one of her great men, within 50 miles of the banks of the Rhine, there would not be a traveller on the waters of that river who would not have made a point of going to see it.

Mr. Goldicutt and Mr. Gutch were appointed by the vestry of Paddington to carry out a design which they had submitted for the new church now in course of erection in the Grand Junction Road. The style is Gothic, and the accommodation is calculated for 1650 persons, 600 of the sittings being free, and reserved for the poor. He had lived long enough to cover in the body of the church, and had just commenced the steeple, to which he purposed devoting great attention, in order to render it a masterpiece of taste in design and skill in execution; but like the lamented architect of St. Dunstan's new church in Fleet Street, the late Mr. Shaw, his fate was not to live to see the completion of a work in which he took the most intense interest up to the moment of his decease. In fact, there never was an architect who felt a more generous and devoted enthusiasm for his art, as all his feelings were sure to be absorbed in any interesting subject which presented itself in connexion with architecture; and if he had a drawing in hand, the midnight hour and the earliest dawn of the morning found him unremitting in his application, until he had completed the pleasing task. His knowledge of

the works of the ancients and moderns was extensive, and he was so feelingly alive to proportion of parts and the effects of light and shade, and of contrast and harmony in colour, that he was continually studying the different parts of his buildings up to the moment of their completion, not being satisfied until he had tried every modification which could tend to improve them. Mr. Goldicutt published some views in Rome, and a series of etchings of views in Italy and Sicily. He was the author of an elegant work on the paintings in the Pompeian buildings, and of an interesting small volume in illustration of Heriot's Hospital at Edinburgh, the plates of which he etched himself.

He has left a widow and 5 sons to lament his irreparable loss, and lies buried in the New Cemetery at Kensal Green. The death of such an artist is a loss to his family, to his friends, and the public. Mr. Goldicutt was Surveyor for the District of St. Clement's Danes, and St. Mary le Strand, and one of the Justices and Commissioners of Sewers for Westminster and Middlesex.

PATENT GUIDE SCREW STOCK.

Manufactured by JOSEPH WHITWORTH & Co. of Manchester.

A. the top plate, fastened by screws, a, a, a. B, a stationary die. C, C, moving dies. D, a sliding piece with inclined sides for moving the dies. E, a nut for drawing up the piece D.

The guide stock is entirely new in principle, and will cut a screw scarcely inferior to that obtained in a slide lathe from a true guide. The name has been chosen from this circumstance, as expressing the peculiar feature of the invention. The thread produced is not only true and of the exact pitch required, but perfectly formed throughout, being cut clean without distortion of the metal.

In all these respects the advantage of the guide over the common stock is remarkable. The latter, it is well known, will not cut a screw in any degree perfect. The thread, besides being irregular, is never of the right pitch. It is also more or less swollen by the violence done to the metal, so that the diameter of the screw is often considerably greater than that of the blank shaft on which it is cut. These defects are attended with the most serious practical inconvenience. They often render it extremely difficult to obtain a fit between the screw and nut, and consequently occasion a considerable sacrifice of time and labour. They necessarily impair, in a very great degree, the efficiency of the screw bolt, which cannot possess either the strength or mechanical power which it would have if the thread were cut true and clean. The defects in question are variously modified according to the size of the master tap used in cutting the dies. If they have been cut by a master tap double the depth of the thread larger in diameter than the shaft to be screwed, they will act very well at first, and the thread will be started true; but as the operation proceeds, they become altogether unsteady and uncertain in their action. If, on the other hand, they have been cut by a master tap of the same size as the shaft to be screwed, the thread is made untrue in its

origin. They first touch the shaft only on the extreme points of their outer edges, as shown in the annexed sketch. They have neither sufficient guide, nor steady abutment, till the operation is on the point of being completed. It is not unusual to employ a master tap of an intermediate size. In this case, however, it is ob-

vious, the dies will combine, in a modified degree, the defects peculiar to each of the cases before mentioned.

In the guide stock this perplexity is entirely obviated, and the dies act with full advantage from the commencement of the operation to its conclusion. They are cut by a master tap double the depth of the thread larger in diameter than the screw blank; while their general form, and the direction in which they are moved forward, are such as to preserve their cutting power and steadiness of action undiminished to the full depth of the thread.

The plan of the guide stock will be easily understood from the sketch prefixed. The interior of the stock is shown in dotted lines through the top plate A. B is a stationary die; C C are moving dies, brought up by a piece D, sliding in a recess in the stock, and bearing with a distinct incline against the back of each die. The piece D is drawn up by a nut E, on the outside of the stock.

The dies having been cut by a full-sized master tap, as before mentioned, the curve made by their outer edges is that of the blank shaft they are intended to screw. Hence in starting the thread, they bear at all points of the common curve, and the impression made by indentation is the exact copy of the thread of the die. The parts indented serve as a steady guide to the dies in cutting round the blank shaft. A groove in the stationary die facilitates the operation. Four cutting edges are brought into action at points of the circumference nearly equidistant, so that by little more than a quarter turn the thread is completely started round the shaft. The difficulty involved in the operation by the common stock is entirely removed.

After starting the thread, the stationary die serves principally as a guide and abutment for the others. The moving dies are peculiar in their form and direction, both peculiarities depending on the position of the arc in the shank of the die. The two sides have each a different inclination to the arc. As the dies move forward, one side becomes prominent towards the screw shaft, and its cutting edge continues in contact with the thread, till it is formed to the full depth required. The prominent sides of the moving dies are those turned towards each other.

The direction of the common die is necessarily towards the axis of the screw shaft. In the guide stock the direction of the moving dies is that of two planes, meeting beyond the centre of the stock, in a line parallel to the axis of the screw shaft, and considerably behind it. This direction is determined by reference to the change which takes place in the relative position of the screw shaft, as the thread is cut deeper. One of the three dies being stationary, there must necessarily be a constant change in the position of the screw shaft in relation to the two others, the effect of which, if not counteracted, would be to deprive the cutting edges of the requisite prominence. By giving them the direction before mentioned, the proper degree of prominence is secured, notwithstanding the change of position. The latter, when combined with the eccentricity of the dies, so far from being any impediment to their action, materially assists it. The newly formed thread is thereby kept in contact with the dies for some distance behind their cutting edges, affording them the same kind of support throughout the operation which they have at its commencement, when, as before observed, the curve made by their outer edges is coincident with that of the screw blank. This continued support, which is necessary to steady their action, could not be obtained without a change in the position of the screw shaft. They would otherwise acquire too much clearance, as they form the thread deeper, and their cutting edges would be apt to dig.

The steadiness of the guide stock, and its easy action in screwing, are equally remarkable. In using it, not one half the force consumed by the common stock is required. The inner edges of the moving dies (which principally act in cutting out the metal,) are filed off to an acute angle. This enables them to cut with extreme ease, and without in any degree distorting the thread, while they take off shavings similar to those cut in a lathe. Their action in cutting is in effect the same as that of a chasing tool, to which they bear an obvious resemblance in form. They may also be sharpened on a grindstone in the same manner.

A practical difficulty has hitherto attended the use of the screw stock, arising from the wear of the taps and dies. The tap becomes less in diameter and consequently taps the hole too small, while the opposite effect takes place with the dies, which, being unable to cut a full-sized thread, leave the screw too large. The only mode of counteracting this two-fold error, so as to obtain a fit between the screw and nut, is by forcing the dies forward, till they have reduced the diameter of the screw a proportionate quantity. From what has been before observed, it is evident that this cannot be done in the case of common dies without injury to the thread. In using the guide stock, on the contrary, it is attended with no disadvantage. Lest the diameter of

work had taken place before the tower was added, with the exception of a slight subsequent disturbance, of which I shall speak presently.

On the north and south walls, immediately above the Norman string course, may be traced a regular series of apertures, *a, b, c, d, e*, Fig. 2, in the face of the wall about 11 inches square, in which were evidently once inserted the beams of a floor or ceiling. These apertures follow the sinking line of the Norman work, and not the level line of the tower work; consequently they indicate the position of the original Norman ceiling, which is now replaced by a vault of the fifteenth century. As the lines of this vault cut through the level of the floor, this last was necessarily removed to make way for it. These holes on the north side, have been rudely stopped up with blocks of tufa—the light substance used in vaulting—from which, we may suppose that the beams were removed and the holes stopped when the vault was in progress, and consequently this material at hand.

At all events, the jointing of the masonry shows very clearly that the floor beams were not removed at the time the walls were carried up; for it is evident that the new masonry was built round and about the beams, in a way that it is not easy to describe, but which plainly shows that the beams were left undisturbed. (Vide Figs. 4 and 5, and the explanation of them at the end of the Report.)

At each angle of the tower, as at *g* and *f*, and at the same level as these beam holes, is a diagonal aperture higher than they are, and extending nearly through the wall; now the purpose of the beam holes cannot be mistaken, and we have seen that the new masonry was built round them without disturbing them, and I conclude that these diagonal holes also received some timber work, which in like manner was allowed to remain undisturbed.

The interior walls of the tower are of a very singular construction: 12 piers, *W*, Fig. 2, on each side, of compact masonry, beside angle piers, are carried up to the height of 26 ft., and connected half-way up by a horizontal course of stone, *X, X*, in long pieces, and by an iron bar, which runs all round immediately under this bonding course. Upon these gigantic *stone gratings*, if I may be allowed the expression, the interior wall of the tower rests; and they also carry the entire weight of the bell-chamber and bells. I believe this construction was entirely adopted for the sake of lightness.

It is clear that it was never intended to be seen from below, for there are no means provided to illuminate the chamber so formed, which at present derives all its light from the apertures in the floor of the bell-chamber above it. The external walls of the tower were at the time of its erection buried in the roof, of which the pitch was much higher than at present; and if windows be now inserted in these walls, I am of opinion, that besides weakening the tower in a manner, which considering its antiquity and shattered state, cannot be recommended, they will prove wholly inadequate to supply sufficient light to the chamber in question; for the piers of the grating are only 4½ in. asunder, with the exception of the middle interval, which is 18 in. Moreover the piers of the grating are of different widths, and their bases irregular, (Figs. 4 and 5,) and the whole has no decorative character; and in addition to the fact that no light was supplied to this room in its original state, which plainly shows that it was never intended to be seen from below, I have shown good reason for supposing that the ceiling which concealed it was only removed to make way for the vault, so that in fact it never was seen from below.

I have now shown, that notwithstanding the shattered state of the piers and arches, the architect of the tower imagined that they might be trusted with the support of his new work. We may at least infer from this, that the settlement had ceased to increase long before the year 1300, for it does not even appear that any attempts were made to repair or fortify the piers for the reception of the new load, with the exception of the north-western. The arch which connects this with the first pier of the nave had a new arch, *Z*, Fig. 2, inserted under it, and the arches which connected this pier with the north transept, both on the ground, at *g*, Fig. 1, and at the triforium, were filled up, leaving only a small doorway below. The ball-flower ornament, which is given to this new pier arch and to a string course on the west wall over this small doorway, serves to show that this work was done at the same time as the tower, which is covered with a profusion of the same ball-flowers.

However, the confidence of the architect in his old piers and arches was unhappily misplaced; the new walls which have been described as resting on the Norman string, exhibit settlements and fractures not nearly so great as those of the Norman work immediately below them, but still of a very alarming character. In the interior of the tower it is evident that the worst of them is due to the fractures of the stones over the apertures, which as already described, were occupied originally by the beams and ancient wood work. At the angles especially, the corner piers of the gratings are carried by large

stones which cover the diagonal apertures, and are thus unsupported in the middle, and these stones have fractured in every instance, allowing the piers to descend more or less. Also the great eastern arch, the crown of which had sunk so considerably before the tower was added, appears to have sunk about an inch subsequently, which has allowed the stone grating on that side to descend, and has produced rents and fractures at its junction with the walls. The outer surface of the tower walls exhibits similar symptoms to those already described of the interior. At the junction of the Norman and Gothic masonry, the same sagging of the old work over the arches, and the same shaping of the new course of masonry to accommodate this sagging, may be observed, and it will also be seen, that the worst and most alarming settlements are in the old work.

Nevertheless it is evident that the dislocations of this old work had proceeded so far as to destroy the cohesion of the walls, and allow crushing of the stone work to begin, which has proceeded, and probably continued from time to time up to the present, and has now reached to such an extent as to make a thorough repair and renewal of the ashling of this portion of the walls necessary to prevent the entire ruin of the tower. The upper part of the tower was originally so substantially built, that when the older portion has been reinstated, this will need comparatively little repair to make it perfectly sound.

Having now disposed of the tower, I will return to its piers in the church below. These piers have evidently been subjected from time to time to a series of repairs and casings which it is not very easy to understand.

I may here refer to a curious document preserved in the archives of the Cathedral which will throw some light upon their history. In this is a bull of Pope John XXII., dated 1319, by which the churches of Shenyngheld and Swalefeld are assigned to the uses of the fabric of the church of Hereford in the usual form. But the preamble recites that whereas sometime since the dean and chapter of Hereford did, upon an ancient foundation which in the opinion of skilful masons was held to be firm and solid, erect a sumptuous building upon which more than 20,000 marks were expended; that now from the weakness of the foundation, this building so threatens ruin, that the entire fabric must be completely repaired from the foundations upwards; which they are unable to undertake, being also burthened with debts incurred in the procuring of the canonization of Thomas of Cantilupe, &c.

This document must allude to the tower and north transept, which were both of them built upon or in connexion with Norman work, the "*fundamentum antiquum*" here mentioned. It is important, as showing that the settlements in the new work, consequent upon its erection on so shattered a substructure, must have begun to show themselves immediately after its completion. But as the repairs which were intended to avert this threatened ruin, appear to have been confined to the piers below, and not to have been extended to the great arches and their ruined spandrels, we may conclude that the settlements were imputed to the failure of the piers alone; and it may be presumed that the movement was arrested, since we find that the present vault was substituted for the wooden ceiling sometime in the fifteenth century, to judge by its mouldings and fashion, and probably at the same time that the similar vault of the south transept was erected; for if the tower were then in a threatening state, it would hardly have been tampered with by such an alteration. It must be confessed, however, that the ribs of this vault are remarkably thin and light, and that it stands completely free of the walls on all sides, resting merely upon the four corbels. This vault must be taken down to obtain proper access to the spandrel walls in the course of the proposed repairs, but it may be replaced.

I will now describe the present state of the four piers in order:—

I have already shown that the south face of the north-west pier was originally traversed by a fissure, which allowed the upper western portion to descend; and it is easy to see that the whole of the Norman ashling to the west of the fissure has been removed and entirely rebuilt. At the upper part, where the shattering and dislocation was the greatest, the face of this new work is brought forwards a few inches; but the remaining portion has the same face as the Norman work, which shows that this repair was not a mere casing like some of the others, but an actual renewal of the original ashlar. This repair is crowned by a Gothic string moulding which lies immediately under the Norman capitals; one of these capitals, *K*, Fig. 2, having been, as I suppose, crushed, has been replaced by a plain block of stone, and the whole of the capitals on the eastern face of this pier have been also removed and the new masonry carried much higher than on the southern face. This work, or at least the southern face of it, is probably an ancient repair consequent on the threatened ruin mentioned in the bull of 1319; but the remaining Norman face of this pier seems in course of time to have again

exhibited threatening symptoms; for it has been fortified in a very singular and unsightly fashion by cramping against its face a shell of masonry, T, 9 in. thick. This masonry is composed of very long and narrow stones set end-long, but is traversed in the middle and terminated at the height of 33 ft. by horizontal courses which serve to bind the work, and probably contain iron bands for the purpose of assisting in keeping the pier together. This casing extends round three sides of the pier, occupying portions of the north and south faces, *n, p*, Fig. 1, and the whole of the east face, *o, o*; but the original Norman shafts still remain upon this latter face to the height of 23 ft., and the surface of the Norman wall, beneath the casing, does not appear to have been broken into. The whole work is apparently the contrivance of a country mason, and as such, its efficacy is not much to be depended upon. The object of the vertical beds may have been to reduce the number of horizontal joints, and thus to avoid or diminish the shrinking of the work, which is always a source of difficulty when new work is united with old. But more probably the evil to be remedied, was a bulging out of the Norman ashlering, like that which now appears on the north face of the south-western pier, and on the spandrels of the great arches, and these long stones were intended to act like the splinters applied to a broken leg.

The north-east pier, A, Fig. 1, is repaired in a totally different manner, being completely cased or enveloped in a coating of solid masonry, Q, R, Fig. 2 laid in the usual manner in horizontal courses, which have thickened out the pier upon the plan 9 in. in every direction, as shown at *a, b, z, z, d, e*, Fig. 1. Whether this masonry is also a mere shell cramped against the undisturbed Norman face of the pier, or whether the Norman ashlering has been removed and the additional work properly bonded into this pier, I cannot tell, but it is very desirable that this fact should be ascertained, as its present efficiency depends very much upon that circumstance. However this may be, it is the work of two different periods. The southern face of the pier shows a nearly vertical fissure or separation of the masonry, and the lines of the beds will be found on examination to be at different levels on the two sides of the fissure which at the bottom and near the top is a mere vertical straight joint. The western half, Q, Fig. 2, of this casing is the more recent of the two, and their line of juncture at present exhibits the appearance of a dangerous crack. This is occasioned by the inevitable shrinking of the late work from the earlier; and as the pier shows no symptoms of giving way in other respects, it does not appear to impair its stability.

The south-eastern pier, B, Fig. 1, retains its Norman face, on a portion of the southern side, *h, g*, but the western and northern faces, as well as the rest of the southern face, have been entirely and substantially rebuilt; for although the present face advances a few inches beyond that of the original Norman pier, it is evident that the Norman ashlering was in this case removed. This pier is in excellent condition, and appears to need no repair or alteration whatever. This work may be attributed to the period immediately succeeding the bull of 1319. The corbel which sustains the tower vault, and which rests upon the string moulding which caps this new ashlering, is formed in such a manner as to show that it was intended to rest upon this string course, and consequently must have been inserted after the string course was completed; the repair therefore in question, must have taken place before the tower vault was inserted in the fifteenth century; but the western face of this pier seems to have been subsequently under-pinned.

The south-western pier, D, Fig. 1, retains on its northern face, *r, s*, a portion of the Norman ashlering, with about 11 ft. of the shafts; above, and to the east of these, from *s* to *t*, the Norman ashlering has been removed and rebuilt, probably in the 14th century, when the other piers were repaired. A long corbel is advanced near the upper part, which carries a projecting pier of masonry, for the purpose of supporting the original Norman capitals, which have been respected and preserved as much as possible throughout all these repairs and alterations. This pier, has at some subsequent period undergone a second repair upon its eastern face, which has been underpinned and brought forward about 10 in. to the east. This work, *t, v*, which is also carried round the southern part of the pier, only extends to 20 ft. in height, and then falls back with a chamfer to the original face. It exhibits no signs of settlement, and appears to have been firmly and substantially executed; but the junction of these three different works upon the plain northern face of this pier, greatly increases the shattered appearance of its masonry, for each boundary line, at first sight, looks like a fissure. Also the half round pier, *r, w*, which received the first arch of the nave, has been rudely cut into for the insertion of the pier of a pointed arch, which has been substituted for the Norman arch on this side of the nave; for as the tower pier in question had declined to the west, as already explained, exactly as the opposite pier had done, the Norman arch, on this side, must have been distorted and shattered in the

same manner as the opposite one, Z, Fig. 2, and probably in so great a degree as to render it necessary to replace it entirely.

In addition to the various repairs of the piers thus detailed, most of the Norman arches in connexion with these piers have been filled up with solid masonry, leaving only doorways. The only one in fact which remains untouched, is the arch which opens between the south transept and the side aisle of the choir. At what period these and the other repairs were executed, it is not easy to determine. However, these fillings up, as well as the piers of the ox-eye masonry, are shown in the plan of Hereford Cathedral given by Browne Willis, in 1727. This is, I believe, the oldest plan extant, for the Monasticon contains no plan of this Cathedral. Perhaps some of these works are due to Bishop Bisse, who is recorded in the former work as having caused the whole fabric to be repaired, and the choir new beautified throughout. He occupied the see from 1712 to 1721. The *ox-eye masonry* is so termed, because the centre of it is pierced by an opening in the form of the ancient *vesica piscis*, called by workmen, an ox-eye.

This masonry, W, Fig. 2, completely fills up the two smaller arches of the tower, namely, the north and south, and is itself supported by two segmental arches branching from an octangular central column. It was, of course, intended to support the arches and tower in their evident state of dilapidation, but it is impossible to conceive a more injudicious or useless work than it presents; in fact, the masonry is so absurdly arranged, that it is unable even to support itself. Its mass has settled in two parts upon its two segmental arches, straightening them and descending and abandoning the arch it was intended to support. The settlements and fissures which now appear in this masonry, are merely the effects of this change of form, and as I do not believe it has had the slightest influence, either for good or evil, upon the building—it may be with safety entirely removed.

I have thus attempted to develop the causes which have brought the building to its present state; and have endeavoured to show that the settlements are of great antiquity, and that many of them are of such a nature, that no apprehensions need be entertained from them, they having taken place immediately after the completion of the work, and not having yielded since; also that many of them have arisen from the injudicious junction of the new work with old. But when the facts of the fall of the west end in 1786, and the evidently impending ruin of the eastern gable of the Lady Chapel are considered, there is too much reason to fear that some of these early settlements may have extended so far, in the first instance, as to weaken and destroy the integrity of the walls, so as to allow them to sink and be crushed under the weight of the subsequent additions. This is evidently the case with the four great Norman arches, the masonry of which and of the spandrel walls above, is in such a state of ruin as to make an immediate repair absolutely necessary for the preservation of the tower. The piers upon which these arches rest, have been, as we have seen, subjected to a series of repairs, many of which have been so substantially executed as to make them perfectly safe. This is especially the case with the south-eastern pier, which is in excellent order, and with the north-eastern, which exhibits only an original vertical fissure, from which nothing need now be apprehended. The two westerly piers are not in such good condition, and these, as we have seen, did, in the first instance, suffer much more from settlement than the others. The mode in which the north-western pier has been repaired or bolstered is unsightly, and may conceal a state of ruin which it is inadequate to prevent. Also the north-western portion of this pier exhibits some fractures, from which there is too much reason to suppose that the heart of the work is in a very unsound condition. For which reasons it would be desirable to remove this casing, and subject this pier to a thorough repair, in the course of which the real state of the internal parts will become evident, and an opinion may be formed of the necessity for a similar operation upon the south-western pier, of which the northern face exhibits in some parts signs of weakness, which may be merely superficial, but which at all events call for examination and repair.

I do not think it necessary or expedient to restore the original form of the Norman piers. The repairs, which are, as I have shown, themselves of a sufficient antiquity to claim respect, have so far advanced the faces of these piers in many places, and removed the Norman shafts in others, and the settlements have so disturbed the capitals from their true positions, that any attempt to restore the original form and to replace the shafts must be attended with very great expense. The existing mode of capping the restored ashlering with a Gothic string, immediately under the Norman capitals, answers every purpose of uniting the two works, with a due regard to appearance.

To the very Rev.

The Dean and Chapter of Hereford,

ROBERT WILLIS.

Cambridge, Oct. 12, 1841.

HEREFORD CATHEDRAL.

FIG. 4.

FIG. 5.

PART OF EAST WALL OF TOWER.

ADDITIONAL REMARKS.

Figs. 4 and 5 (Plate XIV) represent on a scale of $\frac{1}{4}$ inch to a foot, the portions of masonry above the vaults of the tower, for the purpose of exhibiting more clearly the nature of the dislocations and the union of the Gothic masonry with the Norman. In these drawings the separate stones are laid down with great precision from actual measurement to a scale of a $\frac{1}{4}$ of an inch to a foot.

Fig. 4 corresponds to the upper part of Fig. 2, and shows the state of the masonry of the portions of walls marked *r* and *s*, in Fig. 2, as well as the bases of the tower grating.

The surface of the wall below the vault at E and F, (Fig. 4), was covered with paint so that the joints of the masonry could not be seen, but the surface above was easily accessible, and had never been painted or stopped with cement.

Fig. 5 represents the portion of east wall marked *t* in Fig. 3.

In both these drawings A B is the Norman string course, and C D the Gothic string course.

As Fig. 5 is the simplest case I will explain that in the first instance. The Norman string course A B is $3\frac{1}{2}$ in. lower at *b* than it is at *a*, and is besides dislocated; the masonry beneath it is also dislocated and exhibits two great fissures, *c e*, *d f*, of which the first is $2\frac{1}{2}$ in. wide at *e*, and the second $1\frac{1}{2}$ at *f*. The north wall of the tower, shown in section at A, is also thrust back very considerably from its proper place. The masonry above the Norman string course is on the contrary close jointed, its beds remain very nearly level, the Gothic string course C, D having only sunk about $\frac{1}{4}$ an inch in the centre. There is a slight fissure or dislocation at *g*, and in some of the other joints, but not at all of the dangerous character of those in the Norman work below A B. There is also a settlement accompanied by fractures at the angle *k*, but this is occasioned by the sinking of the angle pier M, of the superstructure.

The diagonal aperture N, which extends into the heart of the wall, and in my opinion formerly contained some timber work, was allowed to remain open when the tower was carried up, and the stone *k*, which covered it having fractured, has allowed the angle pier to descend, dragging with it and fracturing the other stones in its neighbourhood, but producing more dislocation in the northern wall, Fig. 4, than in this. In this east wall there can be no doubt that the whole of the Norman work was taken down as far as the level of the string course, A, B, when the tower was carried up, and that the Norman spandrels were at that time in very nearly the same state of settlement as they are now, for the first course of Gothic stones, *a*, *b*, that lie upon the Norman string are cut below to fit the sag of the latter, and their upper bed, *m*, *n*, now is level.

It will also be observed that the next course of stones upon *m*, *n*, has been laid in long thin pieces to give more cohesion to the wall. The smaller fissures at *g* shew that the rotten substructure had sunk subsequently to the erection of the tower.

In Fig. 4 the appearances are more complicated.

In this northern wall there is a row of apertures, G, H, I, K, L, that plainly once received the beams of a floor or ceiling. Now on this side of the tower the Norman string course, A B, is 7 in. lower at A than at B, while the Gothic string course, C D, is level. But the beam holes are equidistant from the Norman string course, and are raised about $5\frac{1}{2}$ in. above it. Plainly, therefore, they belong to the Norman structure and not to the Gothic, for they have sunk together with the Norman work, while the Gothic remains level. When the Gothic work was raised the Norman masonry could not have been taken down on this side completely to the string course, A, B, but the Norman stones beneath the beams must have been at least left undisturbed. That this was the case is clearly seen at K and L, for the stones *k*, *m*, that laid under these beams, are $5\frac{1}{2}$ in. thick, but the stones of the same course *n*, *p*, *q*, are of different thicknesses, *n* being 7 in. and *q* 6 in. so as to restore the level for the upper beds. The little square stones which are packed in at the corners of these holes, and the correspondence of the general level of the intermediate masonry with that of the Gothic string course, all show plainly that although at this end of the wall the beams were undisturbed, yet that the whole of the masonry was removed above them, and on their sides with the exception of the stones, *k* and *m*, that supported them.

At the other end the Norman masonry between the beams, G, H, I, appears to have been quite undisturbed; *r*, *s*, and *t*, are in this case the upper remaining Norman stones, and this is also shown by the fact that the plane of the whole Norman wall, including these stones, is 4 in. in advance of the

Gothic wall above. At the other end, B, (as already mentioned and shown in Fig. 5 at E,) the Norman is driven behind the Gothic wall. Upon examining the wall below the vault at E, the projection just mentioned may be seen to die away to nothing in the middle.

On this face the dislocations of the Norman wall are again much greater than those of the Gothic wall. But it will be seen that the stones of the latter have fractured over every one of the beam apertures. The sinking of the angle pier, M, has also produced a set of crushings in the masonry below.

These figures also show the dissimilarity between the piers of the grating, their different bases and the different widths of their chamfers, some of which again are plain, and some swelled with the usual moulding. Compare for example P, Q, R, Fig. 4.

ECCLESIASTICAL COMMISSIONERS' MONOPOLY AND CRUSADE AGAINST THE EMPLOYMENT OF ARCHITECTS.

SIR—There are no very cheering prospects held out to the architects of this day, if the intentions of the "Ecclesiastical Commissioners" as regards "houses of residence for the Clergy," and of the "Education Commissioners" as regards schools and houses be carried out to the letter. Amongst the regulations adopted by the former Board is the following:—"Every house proposed to be purchased must be surveyed by the architect of the Commissioners; and every new house be built according to his designs, and under his exclusive superintendence." Now in cases of this kind, wherein an outlay of £900, the Commissioners require to have advanced them from £450 to £540, this monopoly of patronage is somewhat startling. Is it to be argued that there are not many architects whom the Clergymen would prefer to employ, whose taste and local knowledge of cost and material would be quite as valuable as that of the London architect to the Commissioners? Surely it would be sufficient that he should exercise controul as to their cost and construction. There would be as much reason in the metropolitan and Diocesan Church Building Societies refusing grants to all applications, but those in which their own architects were employed in the erection or alteration of the churches.

In the case of the Education Commissioners, independently of their having published "cut and dried" plans, elevations, and sections (of very questionable merit) for school houses of every size; applicants are advised, "If their plans do not exactly suit to point out such alterations as may be desired, and the architect of the Commissioners will send down careful drawings of the ground plan and elevation;" and clergymen are advised "not to avail themselves of the services of the local architect until this stage of the proceedings," when he may be "requested to prepare specification and working drawings for the execution of the work." Really this is too impudent! Men of taste and education are not to be supposed capable of properly arranging a trumpery little parish school, and yet are to be called upon to prepare a specification and working drawings to carry out another man's design! I trust no respectable architect will so far forget what is due to his profession as to comply with such proposals.

I must leave to more experienced heads the suggestion of a remedy for these barefaced jobs, (for really they deserve no milder term); I could not refrain from calling attention to them.

Your obedient servant,

London, Oct. 1842.

T. H. W.

[We are sorry to say that there is a strong desire to adopt this centralizing system, not only by the above Commissioners, but also by other public boards, which requires the active perseverance of both professions, the architect and engineer, to counteract. We shall be happy to receive any information on so unjust an encroachment, that we may grapple with such a formidable enemy, and endeavour to put a stop to the system at the onset.—EDITOR.]

WOOD PAVEMENT.—The first wood pavement that was put down in London, at the east end of Oxford Street, four years since, is now being reversed and relaid, and causes much surprise by its great durability, many of the blocks not being reduced half an inch of their original length, which was one foot, though exposed to all the traffic of Oxford Street.

MR. VIGNOLES' LECTURES ON CIVIL ENGINEERING, AT THE LONDON UNIVERSITY COLLEGE.

SECOND COURSE—LECTURE XIV.—WORKING EXPENSES OF RAILWAYS.

Mr. Vignoles commenced by reminding the class, what he hoped they duly felt, that the great object he had had in view during the present course was to consider, in every bearing, the proportion between the cost and expenditure upon any work, as compared with the probable profitable returns. Although this consideration, and that of the good result of any such speculations, might be thought not to come strictly within the duties of an engineer, and until of very late years had been neglected, and, in some striking cases, absolutely repudiated, by eminent men, yet Mr. Vignoles was of opinion that it must ever be kept in view, and should absolutely form a branch of the engineer's study, for he ought to feel that any works he may be called on to construct should not only be such as will reflect credit on him, as a professional man, for design, arrangement, and execution, but, as the Professor had often urged, such as, in this commercial country, where private enterprise and speculation attempts and effects so much, will, by their success, prove the accuracy of his judgment, and his capacity, as an adviser, to lead spirited undertakers into future operations of the same kind. In short, that the success of an engineer depends, perhaps, more on the beneficial results of his works to the proprietors, as commercial speculations, than on his own masterly conquest by art over natural difficulties. But the engineer should further look at this subject in a higher point of view, and consider that all unprofitable expenditure is so much waste of the resources of a country, and that, of all professions in society, his is the one most called upon to direct the laying out of large sums on what may truly be considered national objects, for the judicious and beneficial results whereof he is responsible, and, consequently, whereon his reputation must ultimately depend. Referring to an expression in a late lecture, the Professor observed, that he by no means intended to represent that it was not necessary, in the construction of railways, to reduce the natural undulations of a country to uniform inclinations, but that it was to be maturely considered at what cost such advantage is to be acquired, keeping constantly in view a comparison of this cost with the working expenses of a line more or less perfect. It was the investigation of these *working expenses* that was now to be entered on. In proceeding to do this, Mr. Vignoles observed that he considered it by far the best way to reduce to a mileage not only their gross sum, but also each of the items, these being again subdivided as far as possible. By a "mileage" he understood the result arising from dividing the periodical amount of the expenses by the total number of miles run by locomotive engines *with trains after them*. The Professor insisted that this was the proper way, and gave a number of reasons for his opinion, and for not at all considering the expenses with reference to any proportion they might form of the gross receipts—the two sources of income and expenditure being perfectly independent of each other; and Mr. Vignoles further thought this mileage comparison was the only one from which correct results could be drawn, and whereby materials and experience might be collected, so as to result in the practical benefit of companies being able, before long, to enter into contracts for most of the items of expenditure at given rates. Some companies had already contracted with each other for the supply of locomotive power, carriages, &c. at a mileage; the maintenance of the way was now almost universally paid for by the lineal mile of rail, and he had no doubt but that, after a little more experience, other of the working expenses of railways would form subjects of such a kind of contract.

Mr. Vignoles then proceeded to enumerate the general heads of these expenses, viz. 1, *locomotive power*, subdivided into drivers' wages, fuel, oil, hemp, &c. ordinary repairs, water and fuel stations, reserve fund; 2, *carriages*; 3, *maintenance of line*; 4, *police*; 5, *conducting traffic and stations*; 6, *rates and taxes*; 7, *Government duty*; 8, *miscellaneous charges*; 9, *management*. These were the proper items, exclusive of interest on loans, which, although to be deducted before a dividend could be made, of course formed no part of the positive working expenses of a railway. The Professor then went into a minute analysis of these several items, as actually disbursed on certain railways of various lengths, and particularly of various gradients, explaining the reasons of excess or of diminution in one or other item on the respective lines, exhibiting also comparative tables, and making many valuable observations upon obtaining the best attention and greatest economy from the servants of a public company, by instituting premiums graduated in proportion to the diminution of annual working expenses.

Locomotive power.—In considering this item, Mr. Vignoles showed, from an average of a number of lines, where the arrangements were properly established, and the railway had been long enough at work to have got all matters systematically arranged, the subdivision per mile per train might be taken as follows—viz. wages, 2*d.*; fuel, 4*d.*; oil, hemp, &c., 1*d.*; making 7*d.* per mile as the mere cost of motion, exclusive of repairs of any kind. This might be considered as applicable to an average of six or eight carriages per train. Heavier trains only came occasionally in the course of the 24 hours,

and unless upon lines having exceedingly favourable gradients, auxiliary engines were then applied, the cost and mileage of which being included in the annual accounts, the above rate of calculation would still apply. On railways not having a very considerable traffic, the number of carriages, on the average, were fewer than above stated, and the engine and tender might be fairly taken as constituting half the gross load of each train. The items of wages and oil, hemp, &c. would not materially vary on different lines, except, perhaps, the first, or on short lines with very great traffic, with quarter or half-hour trains, such as the London and Greenwich Railway, the Dublin and Kingstown, &c. The fuel would be a variable quantity, but it would rarely exceed 6*d.* Next must be taken the ordinary repairs, and the Professor stated that in no case was the old adage of "a stitch in time" so applicable as in a constant vigilance and daily inspection and remedy of the smallest defect in locomotive engines. A plentiful stock of engines of the very best materials and workmanship, and an efficient and roomy repairing establishment, though somewhat costly at first, would be found to be the means of keeping down the expense of repairs to a low figure. The amount of this item spread over a year's working appeared to average, on well-regulated lines, about 7*d.* to 8*d.* per mile; some instances had been as low as 6*d.* The expense of water and fuel stations varied from $\frac{1}{2}$ *d.* to $\frac{3}{4}$ *d.* per mile. The reserve fund was an arbitrary charge; Mr. Vignoles assumed that about 10 to 15 per cent. on the ordinary repairs would be sufficient—say 1*½d.* Thus it would seem that the total cost of locomotive power ought to be about 15*d.* or 16*d.* per mile per train. In some instances it had been reduced so low as 1*s.*; in others this amount had swelled to 18*d.* and even up to 2*s.*

Mr. Vignoles then analysed the other heads of the working expenses—viz. carriages, which he seemed to consider an expensive item, varying from 4*d.* to 6*d.* per mile per train—say from $\frac{1}{2}$ *d.* to 1*d.* per carriage per mile, including the various descriptions of vehicles for passenger traffic. The maintenance of the railway varied most remarkably, from 2*d.* per mile per train (which had been the cost on the Dublin and Kingstown Railway, and was now even lower, and Mr. Vignoles believed that on the Greenwich Railway this was also a small item, since they had replaced their stone blocks by timber supports), up to 1*s.* per mile per train, which was the cost on several lines; but, on a railway with the upper works properly constructed, he thought that 6*d.* to 8*d.* per mile per train ought to keep a double road in good order, including a reserve or depreciation fund for renewing the iron rails—a contingency that should by no means be lost sight of. The Professor here made a long digression on this item, as to how much of the cost should be assigned to atmospheric causes, and all collateral and contingent circumstances; how much to the mere dislocation of the upper works; and how much to the positive wear and tear of the iron; and pointed out some remarkable instances of saving in maintenance, where the longitudinal timber bearings had been adopted. The charge of police varied from 1*d.* to 6*d.* per mile per train, according to the vigilance exercised; in placing 2*d.* per mile as an average it was to be considered only as an approximation. Conducting the traffic and stations was an item that did not seem to differ much on the various lines; for the passenger department it appeared to be about 5*d.* Local rates and taxes would, of course, vary materially; the poor rate formed a serious charge on all railways; this item was indirectly contingent on the actual profits of the company; it appeared, however, to be seldom less than 3*d.* per mile per train. Government duty had heretofore been computed at $\frac{1}{2}$ *d.* per passenger per mile—henceforth it was to be calculated at 5 per cent. on the gross receipts for passengers only. This would, of course, make greater discrepancies; still, as the new duty on the gross was estimated to be equivalent to the old duty, an account might be obtained if the number of passengers per train were known. Assuming this number to average forty, taking all the railways of the United Kingdom, the Government duty might be estimated at 5*d.* per mile per train. Taking a mean of four or five railways, the miscellaneous expenses were found to be about 2*d.* and the management about 3*d.* per mile per train. Now, to make a summary of all these, which was, however, to be taken generally, and, of course, liable to be affected in the details, but was still interesting to be submitted in a popular form, and might be useful as giving a comprehensive view of the system:

Abstract of the average working expenses of a railway per mile per train.

Locomotive power—viz. wages, 2 <i>d.</i> ; fuel, 4 <i>d.</i> ; oil, hemp, &c. 1 <i>d.</i> ; ordinary repairs, 7 <i>d.</i> ; water and fuel stations, $\frac{1}{2}$ <i>d.</i> ; reserve fund, $\frac{1}{2}$ <i>d.</i>	s.	d.
Carriages	1	4
Maintenance of line	0	4
Police	0	8
Conducting traffic and stations	0	2
Local rates and taxes	0	5
Government duty on passengers	0	3
Miscellaneous expenses	0	5
Management	0	2
Total	4	0

Mr. Vignoles did not, by any means, pretend that this was other than a probable approximation. Some lines had been worked at a lower rate per mile per train, including all the above expenses; for example, the latest accounts of the North Union Railway show the cost to have been only 3s. 4d., not including any funds for reserve. The Professor himself thought that 3s. was a fair sum, exclusive of taxes and duty, which, however, together form a large proportion of the expense. On the other hand, there were instances in which the expenses had gone up to 5s. per mile per train. He considered it would be a great public benefit if all railway companies, in their reports, would give fuller details of the working expenses, and state the number of miles run by trains. Some few boards set a very good example in this respect. This was sometimes done for locomotive power, but the miles should only be computed as actually run with the trains, and not to include the various extra distances passed over in manœuvres, piloting, signals, &c., which, though necessary, were not part of the actual mileage of trains.

The Professor then drew the attention of the class to the fact, that the locomotive power formed about one-third of the gross expense, and of that one-half only is likely to be affected by the gradient or load, being only one-sixth of the whole of the working expenses, which was but a small item upon which a saving was to be made, to justify a railway being constructed theoretically perfect, unless the traffic was likely to be continued, regular, and very heavy. He further observed, that though he had proposed, for the sake of an easier comparison, to reduce all the items of the working expenses of a railway to a mileage per train, it was manifest that a considerable addition to the number of trains daily, and, of course, to the number of miles run, would very materially affect the locomotive power only. The taxes would be contingent on the receipts; and all the other items would be increased but in a very small degree, on the annual totals, by an increase in the number of the trains, with a carriage or two less at a time. It was important to remember this, as it affected greatly the question of laying out railways. Mr. Vignoles insisted that the extension of railways in England, especially in remote districts, would not be carried into effect until this subject had been more closely analysed, and had become better understood. Looking at the practical working of the Newcastle and Carlisle, the North Union, the Manchester and Leeds, the Sheffield and Manchester, as far as opened, and other lines, all having very heavy gradients, and contrasting their working expenses with those of lines whose inclinations were much more favourable, the average cost per train per mile did not vary greatly. Lines which had been formed at a cost of from £50,000 to £60,000 per mile, a large portion of which was to obtain perfect gradients, seemed to require little less to work them than lines costing only from one-third to one-half that sum. It is true they might be able to carry heavier trains, and did so carry them occasionally, but the average was very nearly what had been stated, and, besides, the public were best accommodated by lighter trains going more frequently. The Professor said, he could only hope that his arguments would draw attention to the subject, and that when, after the analysis of the cost of all the railways had been brought out in the way shown in his last lecture, and that of the working expenses, as in the present one, materials would be obtained for the solution of the problem, of what must be the rule for constructing lines of passenger railways hereafter.

LECTURE XV.—WORKING EXPENCES OF RAILWAYS (continued).

Having, in the last lecture, analysed the working expenses of railways, in reference to the train—that is, reduced to a rate per train per mile, with an average load at the usual velocity, the Professor considered it might be well to consider the same subject in another light. In the preceding mode of calculation no regard was paid to the amount of what might be called the useful weight carried. It seemed to the Professor, that the proportion between the dead weight of the engine, tender, and carriages, and the weight of the passengers and their luggage—in short, between the unprofitable and the profitable load—formed an important element for consideration, even if it did not affect the principle on which railways ought to be worked. In the common omnibus, with a full complement of passengers, the proportion was one to one—taking the average load, about five to three—or including the weight of the horses (the moving power which has also to carry itself) about three to one, or, with a full load of passengers, something less than two to one. But, on the railway, owing to the far greater weight of the carriages, and general arrangement on most lines, the proportion of dead weight is much greater. In a first class carriage, as adapted for long lines, and fully loaded with passengers and their luggage, the proportion is two and a half to one, but, taking the average load, it is about four to one, and, when but little luggage is taken, four and a half and five to one. On short lines, where the trains run often, with many carriages, the proportion is sometimes as high as eight to one, or, including engine and tender, as twelve to one. In an ordinary train of about seven carriages, their weight, and that of the engine and tender, may be taken at about fifty tons; the average number of passengers has, on a former occasion, been shown to be about sixty per train, or four tons without, and, perhaps, five tons with, their ordinary weight of luggage, and say one or two tons of packages and parcels paying freight

being a proportion of six or seven of unprofitable to one of profitable load; and if the carriages were all full, about four and a half or five to one, as above, and on the average, the proportion might very fairly be taken as at least five to one. It appeared to the Professor that there was some radical error here, and that some arrangements were wanting to reduce this proportion, as far as the carriages were concerned, for of course, as long as the locomotive engine was used, its weight would always form a large proportion of the load, particularly with light trains—though the carriages certainly required to be made strong and heavy on this system—and this seemed an inherent defect on this principle of locomotion, perhaps quite irremediable. Yet, at all events, on many lines the proportion of dead weight of carriages was much too great, and might be remedied. Of late this had been done on the Greenwich Railway, where, by combining two classes of seats in the same vehicle, much fewer carriages sufficed. There was a great contrast to this on the Blackwall Railway, where, from having a separate carriage for each station, according to the peculiar mode of working that line, the proportion of dead carriage weight was generally about three, and often four, times as much as on the Greenwich, though the carriages were of the same build. Owing to this and to other causes, extra guards, rope, &c., notwithstanding the generally admitted economy of stationary power, the expense of working the Blackwall Railway, per train per mile, was double what the Professor found was the average for the working on several locomotive lines, and quite as high, if not higher, than the present rate of working on the Brighton Railway, which was the highest of any that had yet come under his cognisance. Although, abstractedly, this over proportion of dead weight carried was not always connected with the moving power, yet an engineer ought to point out, and, when within his control, to remedy such an evil, as the loss consequent on carrying useless weight is equivalent to that arising from increased resistance of gravity in surmounting an unnecessary ascent—a case which every engineer is naturally anxious to avoid.

In the mode of reducing railway expenses to a mileage, adopted in the last lecture, the number of passengers, and their proportion to dead weight of carriages, had not been considered, for it was clear that the arrangement of carriages in any train being supposed to be duly proportioned to the average traffic, any addition to the average assumed load would be pure profit, and would not cause any sensible addition to the cost of the transit of the regular load, for which all the necessary arrangements of engines, tenders, carriages, guards, stations, and the whole working and carrying establishment of the railway was already provided and paid for. But, suppose another mode of considering the working expenses be adopted, viz. from the number of passengers in a train, deduced from an average of many lines for several years, or from any assumed number per train, let the cost per passenger per mile be worked out, and this will lead to the consideration of the true policy for attracting the greatest number of persons, and trying to fill the trains up, as they must go, at any rate.

The Professor then went through the various items of railway expenses stated in the former lecture, and brought them out in decimals of a penny per passenger per mile—the result being, that, taking account of experience gained and applied, and economical arrangements duly introduced, the expense of locomotive power might be taken at $\frac{1}{4}$ d. per passenger per mile, which was coming back to the original estimate made for the working of the London and Birmingham Railway. Other expenses, including Government duty, would bring the total up to two-thirds of a penny, and, under favourable circumstances, of well filled carriages, this might sometimes be brought down to $\frac{1}{4}$ d., but taking the average of lines as now worked, the cost was about 1d. per passenger per mile. On many of the American railways the cost was as low as $\frac{1}{4}$ d., and for long lines on the continent, in India, &c. where wages were low, and coal or wood might be got very cheap for locomotive fuel, and no rates or taxes on profits and passengers were laid, the charge of carrying passengers per mile might be fairly taken at $\frac{1}{4}$ d. only. Now, if the proportion between the unprofitable and the profitable parts of the load were reduced to three to one, as regarded carriages only, and six to one as regards the whole weight of the train, the expense of carrying passengers, taken by weight, will be still at least three times as expensive as carrying goods only at the same velocity, the proportion being of wagons to goods as two to three, and of the whole train, including engine and tender, at less than two to one, and with heavy trains, of goods only, about one to one, and for coal and mineral traffic, at diminished rates of travelling, still less. The Professor observed, that the cost of conveying merchandise might be taken at about 1d. per ton per mile for railway expenses only, exclusive of collection and distribution at the termini of lines, and that of coal and minerals at about $\frac{1}{4}$ d. per ton per mile. With these elements, therefore, of the expense of working railways either per train, or per passenger, or per ton, it is for the politic manager of a public concern to consider what should be the rate of charges above these cost prices to make to the public, so as to induce the greatest amount of traffic. Mr. Vignoles then observed, that there was a third way of considering the subject of the working expenses of railways, in reference to the number of engines employed, which was the mode adopted by the Irish Railway Commissioners, and which was, perhaps, the proper

way of calculating the annual cost on lines of little intercourse, on which, however small the traffic might turn out to be, yet a certain number of engines must be kept to do any work at all. The commissioners, in following out this inquiry, endeavoured to determine the proportion the cost of locomotive power bore to the total working cost of a railway. For the Liverpool and Manchester line it was found that this proportion was only one-fourth the gross annual charges on that line, including much town carriage of goods collected and delivered; but on the Dublin and Kingstown Railway the proportion was, at that time, nearly one-half. It was observed by the Professor, in a digression, that for the average of railways it was now determined to be about one-third. The commissioners finally assumed the cost of locomotive power to be one-third of the total expense of working a line of mixed traffic, and that to run a given number of trains per day, a certain number of engines must be provided; it was then calculated that £1750 a year would be the cost of each engine to work about from 25,000 to 30,000 miles annually, and then they computed the amount of gross receipts necessary to cover those expenses and interest of capital. This was working backwards, to ascertain whether it is justifiable to make a railway at all in certain districts. The result of the commissioners' calculations were, that, supposing there went only two trains daily throughout a given line, the average load of each train ought to consist of either fifty tons of goods or eighty passengers, or a mixed load of twenty-five tons of goods and forty passengers, or in that proportion, in order to justify a line being made—the average charge for passengers being assumed each 1½d. or for goods 2d. per ton per mile, which, it may be observed, is scarcely the half of the average rates of charge on the principal English railways. Mr. Vignoles observed, in conclusion, that having shown that the cost of conveyance of passengers, merchandise, minerals, &c., could be nicely calculated from the experience gained, and could be brought to the definite mileage rates before mentioned, he thought the proper railway charge should be, double the cost for working; which, when the railways had been judiciously constructed, and without extravagance, would sufficiently remunerate the undertakers, as such moderate principle of charging would bring the most traffic.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

May 31.—The President in the Chair.

On the construction of Model Maps, as a better mode than Sectional-plano-graphy for delineating the Drainage and Agricultural Improvements of a Country, or projected lines of Railways, Canals, &c. By John Bailey Denton, Assoc. Inst. C. E.

This communication was accompanied by a map in relief of an estate, as a specimen of the method which the author recommends. The subject of mapping in relief is not new, and the author had previously published a treatise on the subject, but having made extensive experiments, he was enabled to bring the subject before the Institution in a more defined form, showing that the construction of the models had been reduced to a simple and cheap method. These models are peculiarly recommended for pointing out the capabilities of a district for drainage either for agricultural purposes, or for collecting waters together for manufacturing power. They are superior to maps, as they show at a glance the relative heights of the various points, display the geological phenomena, and may be made to delineate the state of cultivation of the districts. The lines of railways, of roads, or of canals, can be more clearly defined upon them, and they are stated to be peculiarly adapted for parish surveys. The expense of making a model of an estate of compact form is stated to be from 2s. 6d. to 3s. 6d. per acre.

"Observations on the Periodical Drainage and Replenishment of the Subterranean Reservoir in the Chalk Basin of London." By the Rev. James Clusterbuck.

This paper, which formed the substance of a letter to the Reverend Dr. Buckland, and was by him communicated to the Institution, consists of a series of observations on the periodical drainage and replenishment of the subterranean reservoir of the chalk basin of London, especially that part of it which lies in a N. W. direction between London and the Chiltern Hills.

The author divides the district into two portions, that to the north and that to the south of the river Colne.

The northern portion is mostly covered only with a bed of gravel, through which the rain water percolates to the chalk, in which, being upheld by the retentive strata below, it accumulates until it finds vent by several deep valleys which incline southward, and carry off a large quantity of water by the streams Ver, Gade, Belbourne, and Chess, into the river Colne, which runs in a S. W. direction under the escarpment formed by the outcrop of the London and plastic clays.

The surface of this reservoir on the water level, regulated by these vents, dipping towards the south at an average inclination of nearly 300 feet in fourteen miles, may be represented by a line drawn from the upper district at an angle, and terminating at the river Colne.

The southern portion is almost entirely covered by the London and plastic clays, from the surface of which the rain water flows in open drains and water-courses. A considerable portion of that which flows towards the Colne, sinks into the subjacent chalk, when it arrives at the outcrop of the sand of the plastic clay formation, and assists in the replenishment of that portion of the reservoir that underlies the London and plastic clays. Here the water level, or the height to which it would rise through perforations in these clays, where its continuity is interrupted by them, would be represented by a line drawn from the Colne to mean tide level in the Thames below London, the only apparent vent for their waters. In the upper district during the replenishment of the reservoir, which usually occurs between December and March inclusive, the water accumulates in a proportion increasing with the distance from the river or vent, and falls off in a corresponding ratio during its periodical exhaustion, which usually takes place between April and November. This alternation of level, which in the upper districts exceeds 50 feet in perpendicular height, would be represented by a line fixed at the river or vent, and rising at an angle proportionate with the increase furthest from it, the extent of its rise or fall being determined by the quantity of rain percolating the chalk. The ratio between these extreme points is so exactly maintained, that if the difference of rise or fall in two wells, one near, and another at a distance from the vent be ascertained, the alternation in the intermediate wells will be determined with considerable accuracy.

The progressive rise of the water level is apparent at the sources of the streams which break out at higher levels in the valleys in which they run, or when brooks or burns burst forth and run during a certain period, when the surface of the reservoir attains a certain level, previously to which, the water rises in every depression till it reaches the height at which it can flow away; the converse of the effects which preceded their bursting may be seen as they cease to flow.

When no water percolates the surface of the upper district, the flooding of the Colne by heavy rains, together with the sinking of the water into the chalk at the outcrop of the sand of the plastic clay formation, raises the level in that locality, and by checking the drainage retards the exhaustion of the reservoir. When this occurs during the replenishment, and from continued rain the level near the river maintains an increased elevation, the water checked in its course towards its vent accumulates in a ratio increasing with its distance from it, a process of adjustment to be traced throughout the district during the replenishment, and conversely during the exhaustion of the reservoir.

The geological condition of the lower portion of the district, together with the paucity of wells, make it difficult to ascertain the extent of the natural alternations of that part of the water level which underlies the London and plastic clays; the difficulty is increased by an unnatural depression caused by the exhaustion of water under London, which is said to increase yearly, and indicates that the rapidity of the demand exceeds that of the supply: the alternation at that point may be from 2 to 4 feet, and is coincident with the rising and falling of the levels in the upper district.

If water be discharged from a shaft in the chalk by a power not capable of exhausting it entirely, the rapidity of the reduction of the level will gradually decrease until it is exactly balanced by that of the supply; when the exhaustion ceases, the level will rise in the inverted ratio of its reduction; if the level be measured in a line from the point of exhaustion, a similar reduction will be found, falling off at an angle decreasing with the distance from it.

The aggregate discharge of water from under London produces a similar effect: daily measurements in one well, confirmed by some coincident measurements in another more than a mile distant, show that beginning on Monday, the level is gradually reduced during the week; the cessation of pumping on Sunday is marked by the rising of the level by Monday morning; if any great quantity of rain falls, a sudden rise or check in the periodical fall takes place; the resumption of any extensive or continued discharge of water may be traced; a general coincidence of rise and fall in different wells is apparent; holiday times, such as Christmas, Easter, and Whitsuntide, may be distinguished. Thus, the measurement of a chalk well in London, would show the days of the week and the great festivals, by the daily variations; the seasons would be indicated by the average difference in the height of the level at different periods of the year; and the changes of the weather by the falling of the rain, would also be shown.

The chalk under London is of a much closer nature than that in the upper districts; it yields the water sparingly but steadily from orifices beneath those beds or bands of flint which are the most unbroken and the strongest, and from faults and cracks which are frequently met with. The constant and increasing demand not only depresses the level under London, but must accelerate the exhaustion of the reservoir above. When the water level near the Colne is suddenly raised by heavy rains, a simultaneous effect is produced on the chalk wells in London. This suggests the possibility of connecting a periodical defalcation of water observed in that stream, and the river Lea on Monday, at those seasons when the water is short, with the exhaustion of water under London. The courses of both these streams is somewhat similar with reference to that place, though they flow in opposite directions. There is some evidence in favour of this supposition, which may

be established when more information is obtained, which will be best effected by keeping registers of the daily variations of wells in different localities, and determining the height at which the water stands with reference to Trinity high-water mark. Such information, if brought together, would well repay the labour bestowed on its collection.

The author's views were illustrated by a number of sketches and enlarged diagrams of the geological formation of the district, &c.

Remarks.—Dr. Buckland was desirous to bring the subject of Mr. Clutterbuck's paper before the Institution, because he was impressed with the value of a systematic series of observations upon a matter so intimately connected with engineering as the theory of the causes of the supply of water to springs and rivers, and the rise of water in Artesian wells.

In his *Bridgewater treatise*, pl. 68 and pl. 69, he had illustrated by diagrams the causes of the accumulation of a subterranean reservoir consisting of sheets of water diffused through strata of gravel, sand, and chalk within the basin of London, and of the rise of water in wells and small perforations through the London clay, under the influence of hydrostatic pressure.

Mr. Clutterbuck's observations and experiments confirmed the general opinion as to the existence of these subterranean sheets of water in the chalk basin, and indicated a connexion between their distant parts, by the sympathy he had observed between the sudden floods at Watford and certain wells in London, the level of which had been carefully observed and found to rise a few hours after the occurrence of the floods at Watford. In London also, he had confirmed observations already made upon deep wells at considerable distances from one another, and found that any large quantity of water taken from one well reduced the level of those adjacent.

It had been questioned whether the communication between wells of this kind took place solely through the medium of large cracks and fissures, or whether the entire masses of the permeable strata, beneath the level of the lowest springs which flowed from them, had all their pores and minutest interstices so entirely filled with water, that any abstraction of this fluid from one well was more or less rapidly replaced by a general flow towards it from every part of the water-logged stratum of sand or gravel or stone in which it was excavated; on the latter hypothesis during such a flow the surrounding wells would be affected in the direct ratio of their proximity to that from which large quantities of water were taken.

It had been found at Brentford that, as the number of Artesian wells increased, the force and quantity of each became diminished; a similar effect followed in the case of adjacent wells in London; the inference he would draw therefore was that a very extensive supply for the metropolis could not be obtained from deep wells of this kind, although a few wells might be supplied abundantly.

The district called the London Basin is made up of a continuous seam of chalk from 300 feet to 500 feet in thickness, which on the S.E. of the Colne is covered with beds of sand and gravel, alternating with plastic clay, and over all these, a thick covering of London clay; whilst the country N. and N.W. of the Colne is for the most part composed of naked chalk. Beneath the whole chalk basin lies a sub-stratum of clay or gault which is impermeable by water, and upholds the reservoir in question. The valleys in this chalk are traversed by the rivers Ver, Gade, and Chess, whose chief perennial supply of water is from springs that issue out of the chalk; in one of these valleys Mr. Dickinson had proved by experiments made with Dalton's rain-gauge (which, being buried 3 feet beneath the surface, received only such water as descended more than that depth) that during about two-thirds of the year the rain which fell rarely sank 3 feet into the earth; but in November, December, January, and February it passed down into the subjacent chalk, in proportions which accorded so constantly with the greater or less amount of rain falling in these four wet months, that he had been accustomed to regulate the amount of orders undertaken to be executed in his paper-mills during the following spring and summer, by the indications on this rain-gauge, of the quantity of water that descended more than 3 feet in the preceding winter.

The Colne is often flooded by the effect of sudden rain which is retained upon the surface of the London clay; but that portion of its water which is derived from perennial springs is supplied from the overflows of the natural reservoirs, or subterranean sheets of water which fill the interstices of the chalk, and also of the sand and gravel beds of the plastic clay formation. The surface of this reservoir is marked by the outbreak of a succession of springs, at levels gradually rising as they are nearer to the upper regions of the chalk; and as the entire supply of this subterranean stock of water is derived from rain that falls on the surface of permeable strata within the London basin, the abstraction of water from any part of this reservoir would, Dr. Buckland conceived, diminish the quantity remaining to be discharged by springs into the rivers in the vicinity of such abstraction, by the total amount of water so transferred to any other than its natural channels.

It was asserted that the surface of the water in this subterranean reservoir did not maintain a horizontal level, but that it rose nearly 300 feet in fourteen miles, between the town of Watford and the highest spring that issued from the neighbouring chalk hills. The molecular attraction of the particles of chalk through which this sheet of water is diffused, and the obstruction presented by friction to its descent through the numerous pores and minute crevices by which it has to pass in adjusting the line of its upper surface, might account for this deviation from the level line which fluids assume, if left to act freely in open spaces, or in large and continuous conduits; Mr. Clutterbuck's repeated observations upon wells along the line in question

must be considered to have proved the existence of this inclined level. His observations were also very important, as to the floods at Watford raising in a few hours the level of the water in deep wells in London, and as to the effect of a steam-engine erected to pump water from a large experimental well near Watford in lowering the water in smaller wells in that town and the country adjacent to it.

Mr. Dickinson had made very accurate observations upon the absorption of water by the chalk, and was convinced of its being always in a wet state almost amounting to saturation; but few crevices and fissures exist in the chalk of the district under notice, the rain therefore occupies a considerable time in overcoming the molecular attraction of the particles through which it passes. Wherever fissures exist at a certain depth below the chalk, they become channels which collect and facilitate the flow of water to maintain the springs; the accumulations of the winter rain sink slowly down in summer, and by a series of vents or springs furnish a supply for the rivers which run in the deepest valleys of the chalk district; a long cessation of rain lowers the level of the water in the rivers, at an interval of some months after the drought, and any extraordinary demand by pumping from the wells in the chalk, would lower the water in the wells around, even at a considerable distance.

From experiments with the rain-gauge buried 3 feet below the surface, he found that but little rain penetrated to that depth until the months of November, December, January, and February—the total quantity per annum was shown to vary between 17 inches and 6 inches, which latter amount sufficed to fill the principal springs. He was induced to believe that if a large supply of water was drawn from the chalk it would eventually have a prejudicial effect in diminishing the water in the rivers of the district.

Mr. Clutterbuck said that the sphere of his observations extended over a line of wells 20 miles in length, and in the whole of them there was the most perfect accordance between the alterations of level of the water and the indications of the rain-gauge, allowing the time necessary for the rain to sink into the chalk; as also there was between the fall and replenishment of the wells at Watford and those in London, whence large quantities of water were obtained by pumping; he could always tell, by measuring the height of water in one well of the series, what would be that of any other well along the line; he therefore was satisfied of the accuracy of the observations in his paper.

Mr. Dickinson observed, that he could not satisfactorily account for the greater amount of variation in the wells at the higher part of the district, when compared with those of the lower part; the alternations of the former amounting frequently to 30 feet, while those of the latter were only 10 feet in the same time.

Dr. Buckland believed this fact to arise from the hydrostatic pressure being less interfered with by friction and capillary attraction, in the lower part of the district than in the upper part.

Mr. Clutterbuck accounted for the alternations of level in the sand springs, being greater than in the chalk springs, by the relative degrees of opposition the water met with, from the friction in passing through the two kinds of strata.

Mr. F. Braithwaite had made many borings and sunk several deep wells into the chalk—he would instance particularly the wells at Messrs. Meux's and Messrs. Reid's breweries, and that at Greenwich Hospital; in these wells he had used cylinders of iron to shut out the sand springs. He did not find the chalk so spongy or saturated with water as had been stated; he imagined that the supply of water was derived from the crevices in the chalk, and in many instances water had not been arrived at, because one of these crevices had been missed, whilst in a well of less depth nearly adjoining, in which they had fortunately hit upon the crevice, a plentiful supply of water was obtained. In the first and second beds of flints under London there was very little water; from the third to the fifth bed the quantity increased, and at 30 feet lower down a continuous fault or crevice was generally found which conveyed a good supply of water—the rise and fall of water in wells in the chalk did not accord with those of wells in the sand beds above the chalk; the alternations in the former amounting to only a few inches in a given time, while those of the latter were as many feet. He placed great confidence in the observations made by Mr. Clutterbuck. That gentleman had told him accurately, from the variations of the well in the Hampstead Road, all the differences of the quantity of water drawn from Messrs. Reid's well, arising either from an extra demand or from cessation in the pumping. The brewers of London could be supplied by the water companies at a cheaper rate than by pumping; but as a large quantity was used for refrigerating the wort, it was important to have the water at a low temperature, they therefore were obliged to pump it up at a great expense. The quantity raised at Messrs. Reid's well was about 7,700 barrels of 36 gallons each per day, which was calculated to be a sufficient supply for 5,000 families; there was already a decided diminution manifested in the supply from the sand springs, and an extension of these effects might be anticipated from the sinking of any large number of wells into the chalk.

Dr. Buckland ascribed the difference of the supply of water in sand springs, and in those originating in chalk, to the relative extent of surface of the sandy and cretaceous strata in Hertfordshire, by which alone they receive their respective supplies of rain water, the amount of sandy surface being to that of naked chalk about as one to twelve.

The rain filters more rapidly through the sand than through the chalk. In beds of hard and compact chalk at great depths, the water sometimes finds no passage except through occasional fissures, but where the chalk is soft, loose and fragmentary, it percolates rapidly.

In the deep well now sinking near Southampton, through London and plastic clay into hard and solid chalk, it would probably be necessary to continue the boring or excavation down into some loose and more permeable stratum below the chalk, before any very large supply of water would be obtained.

Mr. Palmer directed the attention of the meeting to the account of the wells in the London Basin, given in Conybeare and Phillips's Geology (book 1, chap. iv. sect. 11.) It is there stated that at Tottenham, which is about 70 feet above high-water mark, after boring through 123 feet of clay and 2 feet of calcareous sandstone rock, the water rose to within a short distance of the surface in a few hours. At Epping, where the summit of the well is 340 feet above high-water mark, the extreme depth of the bore was 420 feet, but it was abandoned because no water was found; at the end of five months the water rose to within 26 feet of the surface and it has so continued, at 314 feet above high-water mark.

These recorded facts induced him to receive with much caution the statements in Mr. Clutterbuck's paper, especially since he doubted the ready flow of water through the chalk by which the sympathy between the various wells was demonstrated; he had found that chalk might be used as a good puddle for holding water, and therefore as it was certainly more compact when *in situ* than when it had been worked, unless the water flowed along the faults and the beds of flint, he could not understand how it passed so rapidly as had been stated. The chalk no doubt contained some water, but if it was saturated why did not the water in all the wells assume one uniform level instead of heights varying between 20 feet and 314 feet above high-water mark?

Mr. Clutterbuck contended that the main points of his statement were borne out by Mr. Braithwaite's experience at Messrs. Reid's well. A clear distinction must be drawn between the water derived from strata above the clay and that from the chalk; in some elevated spots near London, situated like Hampstead, the clay is capped with gravel, which on being tapped, yielded a supply of water; at Stanmore the water from the gravel at the top of the hill is used; and in a well sunk through the clay at the bottom of the hill, the water stood at 140 feet below the surface. He could not understand why at Epping there should exist any variation from the usual observed facts; the case deserved very careful examination, as it might arise from some local cause. In the course of his observations upon the levels of the wells in London, he found on one occasion that no depression occurred on the Thursday which had hitherto always been the case; he therefore sought for the cause, and found that the Elstree reservoir had been opened on Wednesday, June 1st, which satisfactorily accounted for what had occurred, as from the dry state of the water-course not more than half the quantity of water which passed from the reservoir, reached the river Colne, the rest sank through swallow holes down into the chalk; this showed the attention to collateral circumstances, which was demanded in investigations of this kind.

Mr. Frederick Braithwaite presented and explained a model of a well sunk by him in the year 1841 at Messrs. Reid's brewery, in order to obtain water from the chalk, which had become indispensable, in consequence of the decrease of the supply of water from the sand spring.

On examining the lower part of the well, which had collapsed in 1814, he found that the dimensions of the cast-iron cylinder to be introduced, must be limited to 5 ft. 3 in. by 3 ft. 2 in.; it was commenced at the depth of 87 ft. from the surface, and carried down 135 feet, to within 1 ft. 6 in. of the face of the first bed of flints in the chalk.

Being desirous of retaining all the water from the sand spring, he inserted an internal cylinder which was sunk into the chalk at a depth of 138 feet from the surface, thus effectually shutting out the sand spring from that of the chalk, but permitting the former to flow to its accustomed level in the space between the two cylinders; and to make this supply available in case of need, cocks were inserted in the internal cylinders at convenient depths.

He then proceeded with the excavation in the chalk, increasing the dimensions at every foot in depth, until at 178 feet from the surface, the diameter was 16 feet 6 inches; the excavation was continued at that diameter to a depth of 202 feet from the surface.

In the progress of the work, water was found under the second, sixth, eighth, and tenth beds of flints, and the total supply at this period was two thousand barrels or seventy-two thousand gallons per day of twenty-four hours.

At 196 ft. from the surface the first tunnel was driven 91 ft. N. W. in the direction of another well, which only increased the supply 400 barrels or 14,400 gallons in 24 hours.

The eighth bed of flints, at 154 ft. from the surface yielding the largest quantity of water, (300 barrels or 10,800 gallons per day,) he drove a second tunnel 6 ft. high by 5 ft. wide, for 16 ft. E. to W. and then N. and S. for 108 ft., by which he obtained an increase of 1500 barrels or 54,000 gallons, per day.

Having ascertained by boring, that a further supply of water could be obtained at 20 ft. below, he continued the excavation 22 ft. deeper by 7 ft. diameter, when he found water flowing from two horizontal fissures in the chalk without flints; at that depth he drove 2 tunnels, one N. W. connected

with the first tunnel 91 ft. long, by which he obtained an increase of 3100 barrels or 121,600 gallons per day, the second tunnel in a S. E. direction was driven for 24 ft., when he obtained a further increase of 800 barrels or 28,800 gallons per day.

The total quantity of water thus obtained from the chalk, was 7700 barrels or 277,200 gallons per day of 24 hours, or 192 gallons per minute, forming at the same time a reservoir in the chalk which could contain 100,800 gallon.

He stated the total expense to be under £7000 including the hire and repair of temporary pumps, and the cost of two new sets of permanent pumps.

June 7.—The PRESIDENT in the Chair.

"An Account of the Alterations to Tullow Bridge." By Charles Forth.

The old bridge at Tullow, over the river Slaney, was very dangerous from its steepness, its narrow roadway (only 18 feet wide) and the awkward approaches to it; alterations were therefore determined upon, for which the author submitted a plan and also superintended the execution of it. The floods forbade any diminution of the water-way, and it would have been inconvenient to have raised the approaches on the low banks on either side, flat arches of the following proportions were therefore decided upon.

	Span.	Versed Sine.	Proportion of Versed Sine to Span.	Diameter of Circle of which the Arch is a Segment.
	Feet.	Ft. In.		Feet.
Land Arch . . .	17	0 7	$\frac{1}{16}$	120
Second Arch . .	22	1 6	$\frac{1}{16}$	110
Centre Arch . .	28	2 3	$\frac{1}{16}$	110

The inclination of the roadway was thus reduced from one in seven to one in forty, while at the same time by adding to the abutments on the up-stream side, the width of the roadway was increased from 17 feet to 28 feet, and by completing a portion at a time, the thoroughfare over the bridge was not at any time stopped. For the sake of economy, the work was done in undressed rubble granite with an ashlar face, taking care that the stones abutted well against each other, and on removing the centres, no settlement of any importance took place, and the traffic of loaded cars weighing 35 cwt. each, was carried on without any danger, within a week from the time the arches were keyed. The expense of the alteration was only £485, and it has stood well although it has been subject to some heavy floods.

A detailed drawing of the bridge, before and after the alterations, accompanied the paper, and Mr. Vignoles sent with it an enlarged plan, section, and elevation for the purpose of more fully illustrating what he considered a successful work.

"On the Introduction of Letter-Press Printing for numbering and dating the Notes of the Bank of England." By Thomas Oldham, Assoc. Inst. C. E.

The author commences by noticing the numbering press invented by Mr. Bramah, and adopted in the Bank of England in the year 1809, by which the expense and uncertainty of finishing annually a large number of bank notes, with the pen, was materially diminished, and forgery was rendered more difficult, although the machine was so far incomplete, that it produced only units, the tens and hundreds requiring to be brought forward by hand.

In that year (1809) the late Mr. John Oldham, (the father of the author,) offered unsuccessfully to the Bank of Newry, a machine similar in principle to that of Mr. Bramah, but with the additional power of effecting numerical progression, from one to one hundred thousand by its own operation. In 1813, these machines were adopted at the Bank of Ireland, and one of them was subsequently attached to each press for printing the body of the notes, in order to register and check the number of notes passing through the press.

In the year 1819, Mr. Bryan Donkin invented a counting machine, which is described in vol. 37 of the Transactions of the Society of Arts; it is called "a machine applicable wherever it may be desirable to keep an account of the number of revolutions or strokes, which may be made by the wheels or levers of any other machine, in a given time or space; as for instance, the number of revolutions made by a mill wheel, or of the strokes of a steam-engine beam in a given time, or the number of revolutions made by the wheel of a carriage or perambulator on passing over a certain space." This machine, like all the others used for a similar purpose, depended upon the relative motion of a series of ratchet wheels with projecting rims, having

notches cut in them, so that when the first wheel counted units, the second wheel indicated tens and so on progressively.

The principle of these machines was carried out in a complex manner which required very neat adjustment to prevent their being deranged while working; the author after he succeeded his father as engineer to the Bank of England turned his attention to this point, and the result has been the production of the machine described in the paper.

Four wheels, each divided by 10 notches, leaving a facet between each, engraved with constructive numbers from 1 to 0, are placed upon a shaft, a portion of their breadth being turned down about one-half of their depth, having a boss or collar between each; upon these bosses and filling up the spaces, rest latches, and over each wheel is a pall, the width of the first being equal to that of the unit wheel, and the breadth of the others equaling that of the wheel and latch;—the palls are driven by a crank, by each revolution of which, the first wheel is moved through a space equal to one-tenth of its entire circumference, bringing regularly forward the numbers from 1 to 0, at which point, the latch of the second wheel is depressed, and the wheel moves forward one division, marking the tens; the same process is repeated with regard to the other wheels, and thus any amount of numbers can be registered, by simply increasing the number of the wheels in proportion.

Machines on this plan are now generally adopted in the Bank of England with perfect success, and in some cases they are added to the Braham numbering machines; and as the author believed that they might be adapted to other purposes than Bank-note printing, he presented the drawings and description of them to the Institution.

June 14.—The President in the Chair.

"On Iron Sheathing, broad-headed Nails, and Inner Sheathing for Ships." By J. J. Wilkinson.

These three papers complete the subject which the author commenced in the year 1841, and continued during the present session.*

The first treats of the use of beaten iron, and iron nails, even in very ancient vessels, their corrosion, and consequent abandonment; the attempted introduction of rolled iron for the purpose of sheathing. It touches lightly on the construction of iron vessels, and on various attempts to protect them, which experience has now shown to be unnecessary, as the first iron steamer built by Mr. A. Manby in 1821, at the Horseley iron-works, has been in constant use on the river Seine up to the present period, without showing any symptoms of oxidation, although the only precautions taken, have been to apply a coat of pitch, as often as to a wooden vessel. Extracts are then made from Mr. Grantham's treatise on "Iron as a material for Ship-building."† A list is then given of the patents connected with iron sheathing

and the various modes of preserving it from corrosion, alluding particularly to the valuable labours of Mr. Mallet (of Dublin) on this subject in the archives of the Institution.*

The next division treats of metallic sheathing or a coating of metallic oxide, formed by driving broad-headed nails nearly in contact with each other, into the sheathing board; this process is called filling. The nails used for this purpose by the Romans, were of the same form as those of the present day. There are authentic records of "filling" being generally in use in this country in 1666—but it is conjectured that it was practised much antecedent to that time, and it has continued in use until recently in Swedish and Danish ships. This mode of protecting the piles of harbours and piers from the ravages of the worm is then treated of, and examples are given of its success in various situations.

The third division treats of the inner coating or sheathing, which it has been found necessary to use, independently of the external metallic sheathing. It is stated, that some of the stronger and more adhesive kinds of inner sheathing, have proved mainly instrumental in preserving vessels from sinking, when the outer sheathing has failed or been destroyed.

Hair is noticed as among the earliest materials used for inner sheathing; it was usually applied in a loose state and fixed by pitch or other resinous substances; it was subsequently woven into and used as a cloth—the coarse part of flax was in the time of the Romans bruised and driven between the seams of their galleys. A vessel was discovered in the Mediterranean Sea (between the years 1458 and 1464) in a depth of water of 12 fathoms, where it is supposed to have lain for nearly 1400 years; the deck and sides were covered with paper, linen, and leaden plates. In all the oldest vessels which have been discovered the hair was perfectly fresh, although the timber was in a state of decay, and it is stated that the worm never penetrates through an inner sheathing of hair. In the year 1761, when copper sheathing was introduced, experiments were tried upon different kinds of paper for lining, and after trying white-lead and other substances, thick brown paper dipped in tar was found to be the best.

A list is then given of the patents for different kinds of "felt" now used for inner sheathing—noticing particularly that of Messrs. Borradaile and Co. which appears to be that which is most generally approved. Cocoa-nut fibre and cork, and many other substances, which have been tried at different times, are noticed, and the paper concludes with a copious list of the experiments upon the subject, which the author has compiled from various sources.

"On the Sinking and Tubbing, or Coffering of Pits, as practised in the Coal Districts of the North of England." By Robert Thomas Atkinson, M. Inst. C. E.

This communication describes the means usually adopted in the Northern coal districts, for effecting the "winning" of those valuable mines, and the author expresses the obligation he is under to his uncle Mr. Buddle, to whose valuable documents he had free access during the progress of his labours.

It commences with noticing the early periods of mining, before the introduction of steam power for pumping, when the extraction of coal was almost wholly confined to such tracts as could be drained by free water-courses, "adits," or levels; the chain and bucket pumps, and other limited and expensive means, are then explained, with the principles of free drainage, showing that it was generally only applicable to districts of small extent, and that the best mines were left untouched.

Steam-engines upon Newcomen's principle, were first used in the Newcastle district in the beginning of the last century, and they underwent many modifications, before they were superseded by the Boulton and Watt engines now generally used. The consequence of this introduction of steam power for raising coal, instead of accomplishing it by means of horse gins and other rude contrivances, is that the capability of supply appears only limited by the demand.

Over and above the weight of coal raised, it is necessary to draw immense quantities of water for the purpose of draining the mines. In some collieries the weight of water pumped up, amounts to as much as four times that of the coal raised. At the Percy Main colliery (which is rather an extreme instance) 3922 tons of water are pumped up daily, while only 636 tons of coal are raised in the same time. At the Benwell colliery, which is an average case, the weight of water amounts to 2020 tons per day, and the coals raised to 768 tons or 38 per cent. of the weight of water.

The principal technical mining terms in use in the northern districts, are then explained, and the author proceeds to describe the methods of sinking the shafts, noticing the difficulties which occur in traversing strata of various kinds, and the modes of overcoming them—the temporary timbering with "cribs" and "deals" previous to walling—and the different kinds of "tab-

was employed for sea voyages, and she has been highly successful. She has made three trips to and from South America, and fully realizes all the advantages proposed in her construction."

In a letter from Charles Wye Williams, Esq., dated Dublin, August 21, 1842, he says, "The old iron steamer called the 'Marquess Wellesley,' built for Mr. Grantham at the Horseley Works, is still working and in good order. I went in her recently through Lough Ree and some of the tributary streams that run into the Shannon."—(Sec. Inst. C. E.)

* Minutes of Proceedings, 1840, p. 387, Vol. III.

* Minutes of Proceedings, 1841, pp. 318, 357, and 360, Vol. IV, and 1842, p. 169.

† *Iron as a Material for Ship-building.* By John Grantham. Simpkin and Co., 1842. Pages 6, 7, 8, and 9.

"The first iron steam-vessel, and the first that ever put to sea, was built at the Horseley Iron Works, for the River Seine, and called the 'Aaron Manby,' after the name of the projector and builder. I have lately been favoured by Mr. Manby with the particulars relating to this vessel, which are very interesting as recording the origin of iron steam-vessels. He states in his communication, dated 19th February, 1842, that under a patent which he took out in France for iron steam-boats, in 1820, he, with his friend Captain (now Admiral Sir Charles) Napier, formed a society, and immediately began to construct the first boat at Horseley, but owing to some circumstances connected with the parties at Paris, she was not completed till the end of 1821. She was then sent to London in parts, and put together in the Surrey Canal Dock. She took in a cargo of linseed and iron castings and Captain Napier took charge of her, and navigated her from London direct to Havre, and thence to Paris, without unloading any part of the cargo, she being the first and only vessel of any description that ever went direct from London to Paris. Mr. Manby continues, 'Some time after, I built another iron steam-vessel of the same description, with a few alterations, at Horseley; but, owing to the navigation laws in France, she could not be admitted, and was obliged to be shipped in parts, and I put her together at Charenton, near Paris, where I had then established iron-works, and where I subsequently constructed two other iron steam-boats, the whole for the navigation of the Seine. They continued prosperously at work till 1830, when, owing to the Revolution, and some disputes among the shareholders, they were sold to a new society. In this new society I had no further interest, but they continued navigating up to the period of my quitting France, and I believe are all at work at the present time. From 1822 to 1830 the hull of the 'Aaron Manby' never required any repairs, although she had been repeatedly aground, with her cargo on board.'

"The next iron steam-vessel with which I am acquainted was one built by the Horseley Company, under my father's (Mr. Grantham, sen.) superintendence. This vessel was commenced about the year 1824; was put together in this port (Liverpool), and after a series of delays, crossed the Channel in 1825, and proceeded to her destination, Lough Derg, on the river Shannon. Since then she has been constantly at work, and is now in good condition.

"Shortly after this time, Mr. John Laird of North Birkenhead, commenced building them on a large scale, and has since been extensively and successively engaged in this pursuit. Mr. Fairbairn, of Manchester, also very early took an interest in iron-vessels, and was a party to a series of experiments made at Glasgow, in which iron vessels were employed.

"The 'Ironsides' was the first iron sailing vessel of any magnitude that

bing or coffering" of wood, stone, or cast-iron, used in passing wet portions of the strata or perishable rocks; this part of the subject is treated of very fully, with all the details of the construction of the different kinds and the methods of using them. The cast-iron tubing, which was first introduced by the late Mr. Buddle, is particularly noticed, as is also its use in segments at the Percy pit in the year 1779; some instances are given of the decomposition of cast-iron tubing and pumps, when exposed to the smoke of underground furnaces and the action of mineral water, the combined action of which has been found to reduce the metal to the consistency of plum-bago.

The construction of the pumps, buckets, clacks, rods, &c. composing the apparatus for raising the water from the mines, is then fully described, with the "off-take joints" and the "fish-head" for drawing a "drowned clack." The "hanging sets" or columns of pumps, with their "ground spears" used in sinking the shafts, are also described, with the method of fixing the cisterns at intervals in the shafts, for the different sets of pumps, which are all of the "lifting" kind.

Accounts are then given of the sinking of Percy pit, Flatworth colliery, commenced in 1799—of Howden pit, Percy Main colliery, in 1804—and of a pit at the Barrow Field colliery in 1822, in all of which, great difficulties were encountered.

An explanation is then given of the extensive and complete set of sections of pits, drawings of the machinery, and of the models which accompanied the paper, and the author promises to extend the subject on a future occasion, as this communication is less comprehensive than was intended and has been sent in its present state for the purpose of complying during the session, with the usual condition of election.

June 21.—JAMES SIMPSON in the Chair.

"The History of the Canal of Katwyk, (Holland,) with a Description of the principal Works." By the Chevalier F. W. Conrad, translated by Charles Manby, Secretary, Inst. C. E.

This communication is divided into three parts:—1, The introduction; 2, The history of the Canal of Katwyk; and 3, A description of the principal works.

1. The introduction gives the general outline of the locality of this canal, which is probably one of the most useful and extensive works undertaken in Holland, for the purpose of draining the low lands and rendering them capable of cultivation; it is carried in a north-east direction from the village of Katwyk-binnen through the sand-banks to the North Sea, where it is terminated by five sea locks: it was undertaken for the purpose of draining the district called "Rhymland," a succinct account of which is given, with details of the early attempts at draining, such as the embankments of Ma-rendyk, those of Spaarndam, &c., tracing them up to the time of Count William the Second, king of the Romans, in the year 1253; at which period the level of the district was identical with that of medium tide, and each "Polder" (or spot of cultivated land) was separately protected from the spring tides by an embankment; a change has occurred in the relative levels, whether by the sinking of the land or the elevation of the sea is, it appears, a subject of dispute, but it is certain that the level of the river Y and of the Zuyder Zee is now much above that of the Rhymland district. The natural consequence of this change, has been to increase the demand for artificial drainage by canals, and of windmills for pumping, and also the establishment of local boards of direction, whose duty is the superintendence of the works for the protection of the lowlands.

The district of Rhymland contains 127,000 bonniers or 317,500 English acres, which is thus divided:—

	Bonniers.	English Acres.
1. Polders, or Districts embanked and drained by windmills	54,831	= 137,077.5
2. Lakes and Peat-bog already laid dry	15,262	= 38,155.0
3. Land without mills and sandbanks on the borders of the North Sea	32,630	= 81,575.0
4. Lakes, Canals, Ditches, Peat-bogs abandoned, &c.	24,277	= 60,692.5
	127,000	= 317,500.0

The drainage is effected by 268 windmills, working scoop wheels or Archimedean screws.

Within this district, is included the Lake of Haarlem, which alone extends over 18,000 bonniers or 45,000 English acres; the drainage of it is now commenced and will restore a tract of very valuable land.

The enumeration of the original locks at Spaarndam and other places, is given, showing their incapacity for carrying off the waters, particularly when unfavourable winds prevented their free current into the Y, and hence the necessity for the canal of Katwyk and the choice of that particular spot, which is not affected by the prevailing winds.

2. The historical portion of the memoir, treats of the naturally unfavourable position of the district for drainage; it mentions a project for a canal

at Katwyk in the year 1404, as related by Professor Lulofs,* on the authority of the historian Van Mieris; and enumerates all the various examinations of the levels, the projects of tunnels, canals, &c., the appointment of numerous committees, the local opposition to the several plans, the repairs of the embankments, which had become so expensive that the landholders abandoned their estates, rather than pay the cost of preserving them; the attempt to form a small canal through the sandbanks, which was either closed by a heavy storm or was suffered to fall to decay; the effect of the siege of Leyden by the Spaniards in 1573-4, when instead of draining the country, every attempt was made to cause an influx of the waters to annoy the invading army. It appears that subsequently the expense of renewing the hydraulic works would have been so considerable, that they were in a great measure abandoned for a time. In 1627, attention was again given to the subject, and Katwyk was pointed out as the only spot for an effectual system of drainage. The map by Bolstra, which the author promises to send, shows all the plans with great precision.

The reports are then given of all the various engineers and scientific men, on the drainage of the Lake of Haarlem, in all of which the Canal of Katwyk is a principal feature. The very able tract by Mr. Twent on the state of the drainage of Rhymland, and the necessity for a canal at Katwyk, is mentioned as one of the principal causes for its final construction. After the publication of this tract, Mr. Brunings, in the year 1802, caused the nomination of Mr. Conrad (the father of the author) and Messrs. Blanken, jun. and Kros, to report upon the project; which they did with such effect, that in May 1804, it was ordered to be executed by the reporters, under the superintendence of Mr. Brunings, the director-general of the "Waterstaat;" the plan selected being that which was laid down by Mr. Conrad. In August of the same year, the works were commenced, and in 1805 were so far advanced, that in June the first stone of the inner lock was laid: Mr. Conrad, who in consequence of the decease of Mr. Brunings had assumed the chief direction, carried on the works with such activity, that they were entirely finished by the month of October 1807, without the occurrence of any accident, although they had to support several very severe storms during their progress. On one occasion just as the masonry of the locks was finished the level of the tide was raised by a storm 2.36 metres (2.54 yards) higher than usual, carrying away the external cofferdam, but such was the solidity of the masonry that it resisted perfectly.

A steam-engine was fixed for pumping up a head of water for scouring the sand from the exterior canal; and the final opening of the canal took place with great ceremony on the 21st October, 1807, when a medal was struck to commemorate the event, a copy of which is given by the author to the Institution.

Mr. Conrad made a series of experiments which completely proved the efficacy of the works, and then was carried off within the short space of three months from the termination of his successful labours, which will hand down his name to posterity, as the projector and executor of one of the most useful engineering works on record.

A slight sketch is then given of the origin of the Lake of Haarlem, the causes of its extension, and the works already executed in anticipation of its eventual drainage.

The third part consists of a detailed description of the principal works at Katwyk, with their dimensions, and the necessary references to the drawings which accompany the paper.

The length of the canal from the Rhine to the sand-banks near the lock, is 2260 metres (2471.53 yards) of an average depth of 2.20 metres (2.40 yards) beneath the conventional height of tide for the kingdom of Holland, from which all tidal measures are taken; it corresponds with the average tides of the river Y; the common tide at Katwyk falls 0.60 metres (0.65 yards) below and rises 1.02 metres (1.115 yards) above that standard.

From that lock to the next, is 490 metres (535.86 yards) of the same depth; the additional canal is 1108 metres (1211.70 yards) long, the widths at the standard level vary between 13 and 40 metres, (14.21 and 43.74 yards) and the side slopes, which are all puddled and covered with turf, vary between 1 to 1 and 3 to 1.

The outer canal which has been made chiefly by scouring, is 151 metres (165.13 yards) long, to low-water mark, at a depth of 0.47 metres (0.5139 yards); below that point, it is 37.67 metres (41.19 yards) wide and the sides are constructed of fascines covered with stone.

The principal works enumerated are—

1st. The sea locks (buiten sluis.)

2nd. The interior lock (binnen sluis.)

3rd. A bridge of three arches at the sea locks, with balance gates and rising sluices.

4th. A bridge of two arches over the canal in the Noordwykerweg.

The five sea locks are each 19.78 metres (21.63 yards) long and 3.77 metres (4.12 yards) wide; with the mouths of the out-fall culverts 1.88 metres (2.05 yards) below the standard tide level. They are founded upon piles of red and white deal, with sleepers, and the whole faced and covered with deal plank sheathing.

The masonry of the foundations and of the principal part of the construction, is of blue limestone from Escosine, squared and well bedded. A

* Lulofs' Treatise on the Elevation of the Sea and the Depression of the Land on the coasts of Holland, Transactions of the Society of Haarlem p. 1, f. 88.

hard stone called "klinkers" is also much used for ashlar work, and an inferior quality of stone for rubble-work, with bricks.

The mortar used up to a short distance above the standard tide level, was made from stone lime, and above that, of lime made from sea-shells; cement was also used in several parts.

The modes of constructing these various works are given in minute detail; many of them, differing materially from the English method of construction, possess great interest; particularly those which relate to the embankments and the fascine work.

A description is then given of the Canal of Oegstgeest, which is a prolongation of the Canal of Katwyk for the purpose of bringing into the latter, the waters from the Lake of Haarlem; as well as a means of carrying off the waters of a portion of Rhyndland, during and after the drainage of the lake.

In consequence of the establishment of this canal, the Canal of Katwyk required to be enlarged, which was done to the extent of rendering it 52 metres (56·86 yards) wide, with an average depth of 2·20 metres (2·40 yards) below the standard level. The bridges were also enlarged, and it is now contemplated to add two openings to the inner lock, those of the sea locks being already of sufficient capacity.

Having described the works in detail, the author enters into some general remarks upon the effect produced by the canal, one of the principal being its beneficial use in determining the possibility of draining the Lake of Haarlem. Thirty-five years of experience, have demonstrated that this canal is the surest remedy for the peculiar position of the district of Rhyndland with regard to drainage; the constant action of the North Sea has made no impression upon the simple but solid masonry of the sea locks, in fact, the Canal of Katwyk appears to be one of the most remarkable hydraulic works ever constructed for the protection of Holland.

The author concludes the paper by stating, that although he could with difficulty spare the time from his professional labours on the Amsterdam railway, of which he is the engineer, he was induced to undertake the labour of drawing up this memoir, by the subject being one of those proposed by the Institution of Civil Engineers, in the list for Telford and Walker Premiums for 1842, and by the desire of doing justice to the memory of his father, whose early decease alone prevented his name from becoming as extensively known as his talents deserved.

The paper is illustrated by nine comprehensive drawings and charts, with some lithographic views, a portrait of Mr. Conrad, sen., and the medal which was struck on the occasion of the first opening of the sluices.

"On the Construction of the Bridges on the Bolton and Preston Railway."
By A. J. Adie.

This paper, which was written at the request of General Pasley, and by him communicated to the Institution, contains a description of the bridges over the Cowlin Brook, the Lancaster Canal, and the Chorley Road, which alone possess any peculiarities of construction, and they formed the types upon which the other bridges were built.

In Colonel Sir F. Smith's report upon the Cowlin Brook bridge, he advised great attention being paid to the bridge on account of its "unusual slightness, and the badness of the ground upon which it was founded." The author states, that the latter circumstance induced him to design the present proportions of the work as he wished to reduce the weight of the piers as much as possible; he therefore ventured to deviate from the original design given by Mr. Rastrick. The result has justified his anticipations, as "after the most careful inspection not a single crack nor a splintered stone can be detected."

The ground where this bridge was to be placed, was found to be a rotten and compressible mixture of moss, decayed wood, and sand, with a few large stones; a foundation was made for each pier by driving in piles 20 feet long by 12 inches square; upon these were placed the footing courses of Limerick stone 8 inches thick; the piers were built hollow, so that the utmost weight placed upon each superficial foot should not exceed $5\frac{1}{2}$ tons, which the author states to be a light load for ashlar work:—"In Edinburgh there are old rubble walls 34 in. thick and above 100 ft. high, which in addition to all their proportion of eight floors, and a roof, have $6\frac{1}{2}$ tons on each superficial foot of the bottom courses, and there is a brick chimney in Bolton, the bottom courses of which support $8\frac{1}{2}$ tons on the superficial foot."

The bridge consists of eight arches, each of 30 ft. span; the arch stones are 18 in. thick, of hard sandstone from the Whittle hills, except seven courses at the crown, which are from a better quarry at Ackrington, near Blackburn.

The author then mentions, as a precedent for such dimensions, some arches constructed under Mr. Jardine's direction on the Edinburgh and Dalkeith Railway; they were of Craigleith stone, semi-elliptical in form, of 24 ft. span, with a rise of 4 ft., or $\frac{1}{4}$ th of the span; the stones for these arches were 12 in. deep at the springing, and 9 in. deep at the crown; the abutments of one of them are founded on platforms of timber, without piles, resting upon soft plastic blue clay; they have been standing for upwards of ten years, and exhibit no signs of failure. Another arch is also mentioned, constructed by the same engineer, over the South Esk, near Dalkeith, the span of which is 55 ft., and the versed sine 12 ft.; the keystone is 18 in. deep, and the springers 21 in. in depth.

The author objects to placing a mass of earth upon the haunches of the arch, as, from the tremour caused by the passing of the railway trains, the earth has always a tendency to be wedged in between the side walls and to force them out; he therefore left voids above the arch stones, allowing only sufficient weight of masonry upon the haunches, and thus securing the rapid hardening of the mortar; for this latter reason also the walls of rubble-work never much exceed 3 feet in thickness, and they have been found much stronger in consequence.

The railway is carried over this viaduct on longitudinal bearers, 13 inches deep by 6 inches thick, laid on planks 3 inches thick; the bearers and planks are not fixed together with a view to diminish the vibration of the passing trains: this method of laying is stated to be very effective in this respect.

The Lancaster Canal Bridge was originally intended to have been a direct span of 60 feet, constructed of iron, but the directors subsequently decided on building a skewed stone arch of 25 feet span on the right angle. The arch is semi-elliptical on the square, with a transverse axis of 41 feet 2 inches and a semi-conjugate axis of 8 feet 9 inches; the arch stones are 2 feet 3 inches on the square at the springing, and 1 foot 6 inches at the key-stone; the bed joints intersect at right angles all the lines of sections of the intrados, made by vertical planes, parallel to the elevation; and it is that property that causes the chamfer lines of the beds of the stones to diverge from the springing to the crown. These lines of the curved joints are easily laid down on the sheeting of the centres from a full-sized development, and by lines drawn at different heights, parallel to the springing of the arch. The lines of the radiating bed joints are always perpendicular to the tangent of an ellipse of the same form as the elevation of the bridge, the moulds used to form this being applied in the plane of the elevation. The twist on the length of the beds of the courses was taken from full-sized skeleton moulds of the form of the oblique ellipse or elevation. The five courses running parallel to the abutments are all of the same form and have the same amount of twist on the beds of each stone, except the end stones of the courses, which are varied in length to suit the general breaking of the joints of the courses resting together. The centre part of the arch is plain square work.

This mechanical method of finding the lines, and the twist of the radiating beds for an elliptical skewed arch, is destitute of the scientific accuracy of the mode by which Mr. Buck calculates his spiral lines for oblique bridges, of which the section at right angles to the abutment is an arc of a circle; but the workmen had no difficulty in putting it in practice, and the author states that he would have had more trouble in constructing trussed centres for a flatter curve of a circular arc, and at the same time keeping the towing path of the canal open. He states that he has not met with any description of an arch executed in this manner, but he considers it the only true principle. Every very thin section parallel to the elevation is a proper elliptical arch, and there is a very great saving of stone from the smallness of the twist on the curved beds as compared to the common method of working them.

The Chorley Road Bridge is a compound of the common and skewed arches, which the author finds convenient and economical. He has executed several upon this plan; they are as perfect as the best common arches, and free from skirting of the soffits of the stones. The section of this bridge at right angles shows a rise of 5 feet, with a span of 25 feet. The springers at this part are 15 inches deep, and the key-stone is 13 inches deep; on the oblique section, or the elevation, the span is 37 feet 9 inches, and the rise 5 feet; the springers are 24 inches deep, and the key-stone is 17 inches deep.

The straight part of the arch is formed with courses about 10 inches on the soffit, and these are turned round in curved lines which are portions of circles, the straight parts of the courses being then tangents, and they cut the lines of the elevations at right angles, so that there is no more tendency of the arch to sink at the elevation than would be the case with any elliptical segment of similar dimensions worked in the ordinary way. The part of the acute angle of the arch is formed with courses which converge from the elevation to the abutments, on account of being arcs cutting the elevations at right angles, and then becoming nearly tangential at the springing. The curves for these courses were transferred from the development to the sheeting, in the same way as those for the Lancaster Canal Bridge, and the twist of the beds was taken off full-sized sections of the arch, made in the directions of the converging lines of the extremities, so that at each of these places the beds were worked as if for part of a true elliptical arch, and the beds between the points thus formed were worked off with curved rules found from the development. After the masons got into the way of working this kind of arch, they of their own accord preferred it to the complete skewed arch. In brick work built in this way, it would be very easy to skew the ends of a long archway by having the bricks moulded to the curvature of the key-course, as with a very little alteration they would fit any part of the concentric courses, and a few tapered bricks would facilitate the filling up of the fan-shaped part of the haunch of the acute angle.

The communication was illustrated by several detailed drawings and a model of the bridge, with schedules of the prices and cost of the works.

DR. PAYERNE'S PURIFICATION OF FOUL AIR.

THE notice taken of Dr. Payerne and his diving-bell experiments in the last number of the *Journal*, has elicited a long article in the *Times*, evidently from the same pen which recorded the performances of Dr. Payerne at Spithead. The tone of the article is, however, altogether different from the preceding ones, being rather apologetic than laudatory. Though the writer deprecates the manner in which we analysed the Doctor's performances, he tacitly admits that the result of our analysis is correct;—that nothing, in short, had been accomplished by the apparatus which might not have been done without it. This admission of Dr. Payerne's apologist formed the sum and substance of our remarks, the object being to guard against the adoption of any plans founded on such an unsatisfactory basis. We did not deny Dr. Payerne's power to purify air; we merely asserted that if he possessed such power, he had afforded no sufficient proof of its agency. The insinuation of charlatanism is censured by the writer in the *Times*, but he, at the same time, admits that such an accusation is partly justified by the foolish and absurd paragraphs published in the papers respecting the wonderful powers of a sub-marine boat proposed by Dr. Payerne for navigating the bottom of the ocean; and the writer seems particularly anxious to explain, that Major-General Pasley never sanctioned that peculiar plan of navigation.

Since our former article on this subject was written, we understand that some trials have been made of Dr. Payerne's apparatus in the purification of the air of mines. The experiments are briefly and unsatisfactorily recorded, but they are represented to have fully answered. If the invention be applicable to the purification of foul air in mines, the apparatus will be far more valuable than it could have been in its first proposed application for sub-marine operations; and the Doctor will deserve well of this country for his invention. We confess, however, to have misgivings of such a desirable result, and wait for further proofs. In the mean time, the secrets of the "box" begin to ooze out. The French Academy of Sciences, at some of their recent sittings, have had inventions submitted to them for the purification of air in diving-bells; and though Dr. Payerne's name does not appear in the reports, we imagine that the plans proposed and his are the same. It may be remembered that we before hinted the box might contain highly compressed oxygen gas. This seems actually to form part of the plan submitted to the French Academy of Sciences, but the ingenious inventors propose to use *oxygenated water* instead of oxygen gas alone. Absorption of gas, as well as its generation, is likewise contemplated; for it is proposed to absorb the carbonic acid gas expired from the lungs by caustic lime. If this constitute the whole of Dr. Payerne's secret, we conceive it will avail him nothing. The absorption of carbonic acid gas by caustic lime might possibly be effected on a scale sufficiently great to produce practical results; but unless there be invented some more ready and more economical mode of obtaining oxygenated water than at present known, no real advantage could be derived from the application of any such plan, either for the purification of the air in mines, or for sub-marine explorations.

We subjoin abstracts of the reports read to the French Academy of Sciences to which we have alluded:—

Sept. 26.—A communication was made by M. Thénard, on the means for remaining for a long period in a limited quantity of air, by the absorption of the carbonic acid gas exhaled, and the renewal of oxygen in proportion to its consumption. That the carbonic acid gas exhaled, and which, in excess, becomes fatal, may be absorbed by lime is a well-known fact, but as it is necessary, in the purification of air, to replace the oxygen, which is the vital principle, as well as to get rid of the excess of what is injurious, the great object to be attained in cases where, as in diving bells, it is important to make the same limited volume of air serve for several hours, is to produce oxygen with ease and certainty. M. Thénard proposes to employ oxygenated water, and has shown that not less than 475 times the volume of water of oxygen-gas may be compressed in this vehicle, and subsequently liberated as required. But to produce this result, great care and expense are necessary, and, when obtained, the difficulty of preventing the escape of the oxygen, when not wanted for immediate use, is also very great.

Oct. 3. A communication from M. Sondalo was read, on the means of purifying the air which has been already taken into the lungs from the carbonic acid gas with which it is charged. This gentleman informs the Academy that he remained under water an hour, clothed with a waterproof dress, and having with him, in a small vessel, the preparation of lime required for the absorption of the carbonic acid and the oxygenated water, in order to renew the oxygen of which the air

already breathed had been deprived. With the aid of this small apparatus, contained within his dress, he was able, during the time above stated, to purify the air which he took down with him.

[Since the above was in type and as we were closing the *Journal* we received a communication from Dr. Payerne, commenting on our strictures of last month; we regret that it arrived too late for insertion in the present number, it shall however appear next month.]

THE ECCLESIASTICAL COMMISSION.

[In another part of the *Journal* we have inserted a letter from a Correspondent respecting the conduct of the above commission towards the architects; since then we have procured a copy of the report from which we give the following extracts.]

The commissioners have agreed to certain regulations respecting grants towards providing houses of residence. They are as follow:—

Grants towards purchasing or erecting houses of residence will, for the present, be made only to meet benefactions from other sources, except in cases coming within the third class, and under other special circumstances.

All benefactions must be paid to the commissioners before they can enter into any arrangement either for purchase or for rebuilding.

Every house proposed to be purchased must be surveyed by the architect of the commissioners, and every new house must be built according to his designs and under his exclusive superintendence, the commissioners entering into the necessary contracts.

Plans approved by the commissioners have been transmitted to the several archdeacons, diocesan registrars, bishop's secretaries, and chapter clerks, with a request that they will allow them to be inspected by the clergy; and the plans may also be seen at the office of the commissioners.

Before a contract for building is entered into, reasonable variations in these plans may be allowed, to meet local or other peculiarities; but no extensive deviation from the general design of the commissioners will be permitted, nor any alteration which is calculated to entail additional expense upon succeeding incumbents.

In meeting benefactions towards providing a house, a general rule of proportion will be observed, by which a house built according to the plans of the commissioners (painted, papered, and fitted with grates, bells, &c.), being about £900, the benefaction required will be about £450 in cases of public patronage, and about £540 in cases of private patronage.

"BRITISH ASSOCIATION OF ARCHITECTURAL DRAUGHTSMEN."

The formation of an institution for affording relief to distressed architectural draughtsmen, and for ameliorating the conditions of that class of artists generally is an object which would command our best wishes, and particularly when we see so laudable an effort as the formation of an annual exhibition of architectural drawings conjoined with it; but we are not prepared to admit that the plan now proposed is the best for carrying the object into effect. The rules are too much on the trades-union system to agree with the respectability of the body in question. An annual dinner is doubtless a very good thing, but we do not approve of one levied by fines on the members at large; neither do we think that a dinner is the most appropriate time for our artistic exhibitions. We should, therefore, recommend the abandonment of the whole penal code, the adoption of a more suitable period than August for an exhibition, and an extension of the plan so as to include engineering draughtsmen. The whole system of management must also be revised, and the names of the managers published, and with such amendments, we have no doubt that the plan being well meant will meet with the strong support it highly merits.

Belgian Railroads.—Brussels, Oct. 21.—M. Noel, Inspector of bridges and highways, has visited the whole section of the railway from Courtray to Tournay. Though the buildings are not finished, the road may be opened to the public on the 23rd of October. The Minister of Public Works will be present at the opening. For the present there will be only two trains in a day from Tournay to Brussels, and *vice versa*. With respect to the section of Turcoing, it seems that a trial will be made on the first 10 days of November, and that the inauguration will be on the 15th, when the King has promised to be present. The French trains have arrived at Lille; there is therefore nothing to prevent the trains from immediately beginning to run; but the French train at present takes only passengers, and no goods. The section of St. Saulve will probably be opened about the same time.

the ceiling over the pit. Such accumulation of diminutive stories gives a crowded appearance to the whole, and leaves no space for architectural decoration around the upper part. No doubt a very striking appearance of a different kind presents itself from the pit and from the stage, when the house is entirely filled to the very top; and if we consider merely the coup-d'œil from such points, it may be allowed to be imposing. But then, as regards that part of the audience who occupy the upper part of the house, the arrangement is bad. From the seats which are at all above the level of the top of the curtain, there is only a bird's-eye view of the stage and the scenery, and that only from the front seats, and also facing the stage, for from those on the side of it it is impossible at that height to obtain a sight of the scene or even the actors, unless when they come forward towards the foot-lights. There should be no seats at a greater height than midway that of the curtain, or the level of what is now the second tier of boxes in our large theatres; for, as the scenery can be painted only to one horizon—generally that of the stage itself—its perspective effect is more or less impaired when it is seen from either very much above or below that level. No less preposterous is the practice of continuing the side-boxes up to the proscenium, and sometimes (as in the Opera-house at London) quite up to the very curtain, so that there is no proscenium at all, unless the space on the floor of the stage, between the curtain and foot-lights can be so called. While those who seated lose the scenery altogether, they have the disadvantage of seeing between the wings on the side opposite them; and although the positive inconvenience resulting from such arrangement is felt only by a portion of the audience, the bad effect occasioned by it extends to the whole theatre. Not only ought there to be a distinct proscenium, serving as an architectural frame to the stage and its scenery, dividing that part of the theatre from the rest, but it ought to be of much ampler proportions than are now given it. It should extend so far as to leave some interval—a sort of neutral ground—between the curtain and the boxes, so as to remove the nearest spectator in them to a tolerable distance for properly viewing the stage as a picture; for it is possible to be as inconveniently near the stage as distant from it. Where, in order to contract the stage, or to render the pit and general diameter of the house considerably greater than what is required for the width of the curtain, the plan is made to approach a circle (as is the case in nearly every theatre built within the last 20 years), the boxes should be confined to the semicircle facing the stage; and, so far from being a blank, the curved space on each side between them and the curtain might be made to contribute very much to the architectural appearance of the whole house. This would not take away any thing from the pit, and if it materially diminished the number of the boxes and seats in them, it would be only where there ought to be nothing of the kind. The banishing of boxes from such situations, and making also no more than two tiers, would certainly greatly abridge the present capacities of theatres; a house of the same size would not contain the same number of persons as at present, when a large part of the audience are put where they cannot well see the performance. It is likely, therefore, to be objected that such a system would be too expensive, since a large house would be requisite for a comparatively moderate audience; but curtailments might very well be made elsewhere, for at present the whole building is frequently very much larger and more costly than actual necessity requires, the "house" itself, be its dimensions what they

may, taking up a comparatively small area of the entire plan, while the rest is occupied by stately approaches and saloons, which, where economy rendered it expedient, might be greatly abridged, and much plainer in style, and some of them omitted altogether as superfluous appendages.

In some of the modern continental theatres, the pomp displayed in such accessory parts of the building far exceeds anything of the kind in this country. In that at Berlin, besides several other spacious apartments, is a music-saloon 38 ft. high, 44 wide, and 106 ft. in length in its upper part, where there is a screen of 6 Ionic columns at each end; the whole highly decorated, and forming one of Schinkel's richest pieces of interior architecture. The theatre of Munich has two staircases to the boxes, with flights of marble steps 13 ft. wide; and besides two saloons for the public (each 82 x 31 ft.), there is a very magnificent one communicating with the royal box—not a mere ante-room, but what would be termed a noble room even in a palace, its dimensions being 46 x 44 ft., and 25 in height. In both these theatres, and in that of Genoa, the royal or state box is itself a room of some size, about 15 by 18 ft., more or less; and according to the general custom of the continental theatres, this box (which occupies the height of two tiers, and is adorned with caryatides in front) is directly in the centre of the house, facing the stage, consequently in the very best situation of all; whereas the situation assigned to royal visitors in our theatres is almost the very worst, as far as seeing the stage and the performance is concerned.

In regard to the form of the "house," a decided improvement has taken place of late years; and the circular plan, or one approaching to it (either extended by the curtain being a tangent to the circle or somewhat beyond it, or reduced by the curtain intersecting and forming a chord to the segment), may now be considered the one established as being the most pleasing and commodious—that which is best adapted for affording a distinct view of the stage to the majority of the audience. But there is considerable difference of opinion as to its being the best form in regard to hearing. In fact, the science of acoustics is not yet brought to exactness as regards practical purposes in building: it is easy enough to ascertain beforehand how much of the stage will be visible from different parts of the theatre, but not so what will be the result as to sound, since that will depend upon a variety of circumstances, some of them counteracting each other, and not every one of them to be guarded against or foreseen. The shape of the house is but one of them out of many: much will also depend upon size, much upon the depth of the boxes and galleries, and also upon accidental and such trivial matters, that any defect of advantage so occasioned is not likely to be traced to them. Here the chief guide is experience; and experience seems at present to be in favour of, at least not at all against, the circular form; for the new theatres at Mayence, Dresden, and other places where it has been adopted, are said to be perfectly satisfactory in regard to the actors being distinctly heard in every part.

The article concludes with a table of modern theatres, drawn up on the same plan as some of the other very useful tabular synopses attached to previous architectural articles in this Cyclopædia, and from which we have occasionally borrowed. In the present instance we must content ourselves with a small portion, namely that section of the table which relates to Germany and Belgium.

GERMANY AND BELGIUM.

	Architect.	Date.	Width of curtain.	From Curtain to Back of Pit.	Greatest Breadth of pit.	Height from Floor of Pit.	Stage.
Berlin, Opera-house	Von Knobelsdorf	1740-3	26	64	42	58	50 deep 52 wide
" Great Theatre	Schinkel	1816	43	62		44	66 deep 86 wide
Dresden	Semper	1837-1841					A magnificent structure, with Grecian Ionic hexastyle portico on a lofty flight of steps.
Hamburg	Schinkel	1826-7	40	69 to back of boxes	50	56	60 deep 80 wide

Ghent	Roelandt	1837-9	37	59	42		60 deep 78 wide
							Facade 300 feet. Oval saloon 91 x 59, making, with smaller saloon and concert-room, an extent of 270 feet.

Electrotype Manipulation, Parts I and II. By Charles V. Walker. Tenth edition.

This little manual, published by Messrs. Knight and Sons, contains a most complete account of the whole process of electrotype manipulation, so that by its instructions any novice may become a proficient in this interesting art. The first part is devoted more particularly to the reproduction of medals. It enters largely into the consideration of those difficulties which may be expected to present themselves to the unexperienced, and states clearly the modes by which they may be avoided. The second part of the work relates to the more general applications of electrotype in the arts, particularly those of plating, gilding and etching. The directions are given minutely and clearly, and with a view to conduct the experiments by the most economical means. We have seldom, indeed, met with a work professing to give instructions in the manipulation of any art or process of manufacture so practically useful as this small volume.

Gas Meters—their Unfairness Demonstrated. By HENRY FLOWER. London: G. Mann, 1842.

This pamphlet explains the construction of the gas meter, and in what manner it may be affected so as to show a false register of the quantity of gas consumed, to the great loss of the consumer.

"An undue quantity of water in a meter will make a difference of about 20 per cent. in the amount registered over the quantity actually consumed, but let the water in a meter be ever so nicely apportioned, still the consumer will sustain a loss of something like 10 per cent.

"Blame, therefore, attaches both to the consumer and to the Companies, but more especially to the latter. It is not to be supposed that the consumer can enter into the niceties of a complex machine like a meter. The Gas Companies take good heed that the meters shall not and cannot give more than a nominal thousand feet for the thousand feet registered, which my experience shows to be not nine hundred feet for "the thousand," but they leave their tenants to run the risk of defrauding themselves out of from 1 to 20 per cent. of gas as well. If, as the companies construct their meters, that too little water in them will occasion an impossibility of obtaining a supply of gas, why should they not be so gauged as to declare to the consumer, that if he has above a certain quantity of water in his meter, that he is registering water as well as gas?"

At the conclusion, Mr. Flower explains Mr. Lowe's ingenious plan for naphthalising coal gas, which appears to be an invention of great importance.

A Series of Diagrams Illustrative of Mechanical and Practical Philosophy and their Practical Application. London, Chapman and Hall, Part III. (Published under the superintendence of the Useful Knowledge Society.)

The present number, which illustrates the wheel's axle, has shown several practical applications of that power. For instance, we have toothed gear, the crane, friction bands, and a circular saw. Thus, a more mechanical turn has been given to the work, and we can anticipate that it will in its progress form a portfolio of working drawings of all the principal machinery and mechanical applications, suitable for the mechanics' institutions and the workshops, and for instruction in all our colleges and academies; for such views its value is much increased.

Professor Hosking, of King's College, is preparing for publication "Professional Notes on some of the Flemish and Rhenish Churches, made during a recent tour in Flanders and Germany, with notices of the Belgian and Prussian Railways, and of the railway works now in progress between Liege and Aix-la-Chapelle"—and he has in the press, a work "On the Principles and Practice of Architecture, with Remarks on the modern practice of Competition."

THE TEMPLE CHURCH.

THE restoration and repair of the Temple church, at once the most beautiful and perfect memorial of the Order of Knights Templars now in existence, cannot fail to be a subject of congratulation to the country at large. It is pleasant to reflect that beneath the surface of this bustling and money-loving world there is a strong undercurrent of enlightened feeling respecting the care of our national edifices. The ancient abbey of St. Alban's, Crosby Palace, and Our Lady's Chapel, Southwark, are among the more recent structures preserved from decay by the honourable and ready contributions of subscribers from all ranks of society. The expense and magnificence of the repairs in the Temple Church promise to surpass any similar attempt in this country, the whole of the enormous outlay required being jointly borne by the two societies of the Inner and Middle Temple.

Those persons to whom the Temple Church was familiar in its late dress of plaster and whitewash will scarcely recognize the ancient structure in the gorgeously decorated appearance it now presents. The repairs were commenced in 1840. The dilapidated state of the building, in great measure owing to the reckless manner in which the walls and pillars had been overlaid with heavy monuments, rendered these works necessary, and, in accordance with the improved taste now prevalent in the public mind, the benches were led to extend the mere repair into a restoration of the building as nearly as possible to its original state. The architect who commenced these works was Mr. Savage, but owing to some differences between that gentleman and the building committee of benchers, the charge was transferred to Mr. S. Smirke on the part of the Inner Temple, and Mr. S. Burton, on that of the Middle Temple. It is, however, due to Mr. Savage to state, that the plans prepared by himself have been in a great measure carried out by his successors.

THE ENTRANCE PORCH is for the most part new, the excessively ornamented old doorway having been partly renewed, and the remainder reworked and restored.

THE CIRCULAR NAVE.—The six clusters of old Purbeck marble columns, which formerly supported the whole superstructure, have been removed and new columns of the same material substituted. The ceiling of the centre part (a truncated dome of comparatively modern erection) has been taken down, and a new oak vaulted and grained ceiling substituted, painted by Mr. Willement, strictly in accordance with the style of the period. The whole of the walls, arches, and aisle vaults have been reworked, and new polished marble shafts substituted for the old columns. The sculptural figures of the Knights Templars have been restored in the most perfect manner, and will again occupy their former positions.

THE TAIPORIUM OF THE NAVE has been converted into a depository for nearly all the monuments which formerly disfigured the walls of the church. This gallery, common in all cathedral edifices, now forms a handsome promenade of 12 feet wide and 15 feet high round the circle, the mural tablets of most of the eminent lawyers of the last two centuries being carefully arranged on either side. They are much better seen than formerly, and form an interesting collection of monumental sculpture.

THE SQUARE CHANCEL.—This part of the church, hitherto filled with pews, which concealed the bases of the marble columns (themselves hidden by a thick coating of plaster and paint, through the over-anxious desire to efface all emblems of the Popish faith on the part of the Protestant lawyers shortly after the reformation), and encumbered to a height of eight feet from the ground with oak wainscoting, shutting out the view of the elegant marble piscina on the south side of the building, has been entirely cleared of these unsightly additions. The huge pulpit and organ screen are also removed, and a new and elegant gallery for the reception of that instrument has been erected on the north side, occupying one bay, with a vestry beneath. The walls of the latter small apartment are studded with monuments, among which the most conspicuous are those of Lord Eldon, Lord Stowell, and Oliver Goldsmith. The north and side aisles are each divided into five compartments; the eastern division will be occupied by the benchers ladies, and that adjoining by the benchers themselves, every seat having distinct and elaborately carved elbows. The two next are occupied by the barristers, and the remaining division by the barristers' ladies. The members of the Inner Temple will occupy the south, and those of the Middle Temple the northern side of the church. The whole of the centre is fitted up with sittings for the students, in the cathedral style of arrangement. The most prominent object on entering the chancel from the western porch is the triple-lancet window over the altar. This beautiful specimen of stained glass, executed by Mr. Willement, F.S.A., is intended to represent the principal events in the life of our Saviour.

The prevailing colours used for the decoration of the walls and roof of the chancel are blue and red. The ceiling is divided into compartments, alternately ornamented with the armorial bearings of the two Inns. Figures of several of the early kings of England are emblazoned on the western wall, and the shield of the holy cross worn by the Knights Templars is frequently introduced. The altar is entirely new, from the design of Mr. Smirke. The creed and commandments are painted black, on a gold ground, with illuminated initials, producing a remarkable richness of effect. The whole of the designs for the stall-ends and elbows, consisting of grotesque heads and foliage of the most elaborate description, have been furnished by Mr. Cottingham, of the Waterloo-road.

The floor is paved with glazed encaustic tiles, copied exactly from ancient examples.

The bell, which was formerly in the roof of the circular nave (although that was not its original place), has been removed, and hung in a new stone belfry turret erected over the Newell staircase on the north side.

THE NEW ROYAL STABLES AND RIDING-HOUSE AT WINDSOR.

These extensive buildings have just been completed (the sum expended having been brought within the amount of the Parliamentary grant of £70,000), according to the original designs of the late Sir Jeffrey Wyattville, under the immediate superintendence of Mr. Ashton, his successor. Messrs. Grissell & Peto were the builders employed.

The buildings (the architectural style of which is in perfect keeping with that of the Castle) are on the south side of, and about 150 yards from, the Royal residence. The whole frontage, towards the Home Park, extends to upwards of 300 feet. The stabling and coach-house department occupies three large quadrangles, quite distinct from each other being divided by high stone walls.

Accommodation is afforded, in the aggregate, for 102 horses (exclusive of 13 loose boxes) and 36 carriages.

In the angles of each quadrangle are extensive forage lofts, constructed with every regard to convenience. Each quadrangle contains extensive saddle and harness-rooms, cleaning-rooms, and other appropriate and necessary offices, with water laid on throughout, large coppers for heating water, extensive dung-pits, and other appurtenances. The harness-rooms, which are heated by stoves, are about 20 feet square. The cleaning-rooms are of rather larger dimensions. The coachhouses, which are very lofty, are heated by means of hot air. Some idea may be formed of their dimensions, when it is stated that the extent of room appropriated for each carriage is 8 feet in the width, and 20 feet in length. An apparatus for heating water for the use of the men, and for warming the coach-houses, &c. is attached to each quadrangle and situated in the basement, with pipes communicating to every part of the building where it will be required.

The width of each stable, from the back of the manger to the opposite wall, is 22 feet—thus allowing plenty of space for the men behind the heels of the horses. Each of the stables, which are ventilated by means of an admirable contrivance, through an aperture leading to the roof (and which can be opened or closed at pleasure), will be lighted at night by gas. The whole of the flooring is composed of Dutch clinkers. In the centre of each stall are iron gratings, communicating with cross drains which run into the heel drains, under the flooring of Dutch clinkers, and through these, by merely turning a tap at the upper end of the stable, a strong course of water is forced, cleaning every accumulation away from the under drains into the common sewer to the river.

The poney stalls, the partitions of which are exceedingly massive, and constructed of highly polished oak, are 13 feet long and 6 feet wide. The stalls (the same material being used for the partitions throughout the stabling department) for the carriage and riding-horses are a little larger. The fronts of the mangers, and also the walls at their backs, extending 4 feet in height, to the top of the hay-racks, are of slate. The front upper edges of the mangers consist of a revolving cast iron roller, about 3 inches in diameter, extending their whole length; thus offering an insuperable bar to the practice of crib-biting.

The new riding-school, as has been before observed, divides the upper or northern quadrangle from the centre one. This spacious building is 170 feet in length, 52 feet in width, and nearly 40 feet in height. At night three splendid gas chandeliers along the centre of the building diffuse a clear and steady light throughout the interior. Over the riding-school are most convenient dormitories for the use of the single men connected with the stables; these consist of 30 apartments.

ST. GEORGE'S CHAPEL ROYAL.

THIS beautiful chapel was re-opened for divine service on Sunday morning, 23d ult., after having been closed for some days to enable the workmen to complete the large west window, and another of stained glass in the choir. The following description of the former window will enable the reader to appreciate more justly the alterations:—

In the year 1774, the Rev. Dr. Lockman, canon of Windsor, collected, from various parts of the chapel, a great number of detached figures in stained glass. These were placed in the compartments of the great west window, on a ground of plain white glass. The number of figures not being sufficient, however, to fill the whole of the openings, the glazier ingeniously composed some trellice patterns, which were formed in colours of the most discordant kind, to fill the remainder. The ramifications of the arched head were occupied by plain surfaces, chiefly of glaring orange and purple-stained glass; yet, with all these violations of good taste, perpetrated at the expense of the then chapter of 600*l.*, there was a certain degree of effect produced, particularly at sunset, which gave great brilliancy to the architecture.

In the new arrangement by Mr. Willement, the whole of the ancient figures have been repaired, and instead of the crude ground of white glass, on which they were placed, each compartment has a dispersed ground of a warm yet quiet tint, with an architectural frame to each, formed by a base,

columns, and enriched canopy, corresponding in design with the style of the chapel. Ten ancient figures, and as many entirely new, have superseded the formal and patterns of the glazier. The lowest range of openings being considerably higher than the others, that space is now occupied most appropriately by a long label inscribed with the prayer, "God save our gracious Sovereign, and all the Companions of the Most Hon. and Noble Order of the Garter."

Within the arched head of the window the four principal compartments are filled by the initials, crown, and badges of King Edward III., the founder of Order of the Garter; of King Edward IV., who began the erection of the present chapel; of King Henry VIII., who completed it; and of Queen Elizabeth, in whose reign so many additions were made to the Castle. The smaller openings are strewn with the Tudor devices on rich grounds of ruby and garter blue; in the centre, above a sculptured panel of the Royal arms, are placed in stained glass the arms of the patron saint, with the initials of Sanctus Georgius; and above these, in the extreme apex, the sacred monogram I. H. S. By these judicious alterations, the whole surface of the window has become replete with the richest tints, sufficiently varied to obviate any monotony, and producing, with the greatest fullness of tone, an entire absence of that unseemly glare which too often pervades almost all modern attempts in this class of art. The arrangement conduces essentially to develop the great beauty of the stonework—a point most sadly neglected in most cases.

Dorsetshire.—The roof of St. Mary's Church, Wareham, having been found about two years ago to be in a very decayed condition, and the accommodation being inconvenient, and the pews cold and damp, the rector and churchwardens had it surveyed by Mr. Donaldson, who ultimately furnished drawings for rebuilding the body of the church, providing accommodation for 1000 persons, 600 being devoted to the poor. The tower and chancel, which are fine specimens of simple ecclesiastical Gothic, still remain, and the church has been executed in the same style to accord with them. The new body consists of a nave separated from the lateral aisles by three octagonal piers on each side, surmounted by lofty arches, above which rises the clerestory with its ceilings to the height of 40 feet above the pavement of the nave. The church was re-opened for public worship on Michaelmas-day, the Bishop of Salisbury and a numerous body of the clergy assisting on the occasion. Some very curious fragments of a very old date, possibly as remote as the Saxon times, were dug up or discovered worked up in the old walls, and have been carefully preserved as memorials of the antiquity of the sacred edifice, which must have been built and rebuilt three or four times.

Architecture on the Continent.—In speaking of Cologne Cathedral, the *Athenaeum* observes that something of the same spirit of reparation and restoration and completion of ancient monuments, which has set these vast works in progress, is diffusing itself very generally over the Continent. Our readers have learnt how actively this taste for the renewal and perfection of historical monuments has been engaged in France; and Belgium has not been behindhand in the work of restoration. The two towers of Sainte-Gudule, at Brussels, have been carefully repaired, and all the delicate tracery which time had injured has been renewed, stone by stone. The church of Notre Dame de Finisterre is surrounded by scaffoldings, which announce extensive repairs. So with the light and graceful spire of the Cathedral at Antwerp, "whose 622 steps" it is said, "may now be ascended, and the upper gallery reached, without the adventurer fearing to be carried away by the wind, in company with some decayed and tottering pinnacle." In the same structure, M. Geerst is still labouring at the Gothic stalls, which are said to be master-pieces of their kind. At Ghent, the Cathedral of Saint-Bavon is in course of complete restoration. At Bruges, the churches of Saint Salvador, of Notre-Dome, and the chapel of Saint Basil, have been repaired; and the venerable Cathedral of Tournai, the most ancient religious monument in Belgium, has, for upwards of a year, been the subject of important works intended at once to strengthen it and restore its ancient character. The Hotel-de-Ville, of Louvain, unequalled for the delicacy of its fretwork and tracery—a gem without rival in the florid-Gothic style, has also been carefully restored—and the Hotel-de-Ville of Brussels is now in course of restoration.

St. Martin's Church.—The steeple of this church, which was struck by lightning about three months ago, and suffered such extensive damage as to render it necessary to be taken down, has just been rebuilt, and was on Tuesday, the 10th ult., finally completed. The contract was undertaken by Mr. Hemming, of Regent Street, for the sum of £1000*l.*, which included the taking down of the old steeple and the building of the new one, and which sum will be paid by the Phoenix and Sun insurance-offices, by whom the church was insured about four years ago. The ball and vane on the summit have been regilt, and present a very showy appearance.

Bologna.—Academy of Fine Arts.—The programme has been published by the Academy of Fine Arts for the competition for 1843. We merely give the subject proposed for Architecture. Designs for a Custom-house on a great scale, for a large city. Besides the elevations of the building, there must be given, on a larger scale, separate drawings of the principal parts, and a clear account of the artist's views as to the disposition of the whole.

Rentals of Metropolitan Commissioners of Sewers, North of the Thames.—Westminster, &c., commission, £2,788,190; Holborn and Finsbury, £1,316,013; Tower Hamlets, £888,596; City of London, 792,904; Poplar, £78,411; St. Katharine's, £12,964. Total, £5,877,078. The city of London having sent in no return, the above amount is taken from their return to the House of Commons in August 1834.

Bricks lighter than Water.—Some bricks made of a clay of a portion of the soil of Berlin, which, on account of the quantity of fossil infusoria contained in it, will float in water.

ELECTRO-MAGNETIC RAILWAY LOCOMOTIVE.

A trial of this very ingenious machine, constructed by Mr. Davidson, was made last month on the Edinburgh and Glasgow Railway, in presence of a number of gentlemen, many of whom were eminent for their scientific knowledge. The construction of the carriage is the first attempt which has been made in this country to apply the powers of electro-magnetism to railway traffic, and from the success which attended this trial, sanguine hopes may be entertained that the period is not distant when it will either supersede, in many cases, the employment of steam, or lend a powerful aid to this mighty instrument in all the operations in which it is at present employed. The carriage was impelled along the railway about a mile and a half, and travelled at the rate of upwards of four miles an hour, a rate which might be increased by giving greater power to the batteries, and enlarging the diameter of the wheels. We understand that the carriage was built at the expense of the Railway Company, and we cannot but congratulate them in having the discernment to employ Mr. Davidson, a gentleman of much practical knowledge and talent, to whose genius great discoveries have been made in electro-magnetism, by whom the carriage was projected, and to whose unwearied exertions the practicability of the scheme is almost placed beyond a doubt.

The dimensions of the carriage are 16 feet long by 7 feet wide, and is propelled by 8 powerful electro-magnets. The carriage is supported by four wheels of 3 feet diameter. On each of the two axles there is a wooden cylinder, on which are fastened three bars of iron at equal distances from each other, and extending from end to end of the cylinder. On each side of the cylinder, and resting on the carriage, there are two powerful electro-magnets. When the first bar on the cylinder has passed the faces of two of these magnets, the current of galvanism is then let on to the other two magnets. They immediately pull the second bar until it comes opposite them. The current is then cut off from these two magnets, and is let on to the other two. Again they pull the third bar until it comes opposite, and so on—the current of galvanism being always cut off from the one pair of magnets when it is let on to the other.

The manner in which the current is cut off and let on is simply this:—At each end of the axles there is a small wooden cylinder, one-half of which is covered by a hoop of copper; the other is divided alternately with copper and wood (three parts of wood and three of copper). One end of the coil of wire which surrounds the four electro-magnets, presses on one of these cylinders, on the part which is divided with copper and wood; the other end of the coil presses on the other cylinder in the same manner. One end of the wires or conductors which comes from the battery, presses constantly on the undivided part of the copper on each cylinder. When one of the iron bars on the wooden cylinder has passed the faces of two magnets, the current of galvanism is let on to the other two magnets, by one end of the coil which surrounds the magnets, passing from the wood to the copper, and thereby forming a connexion with the battery. This wire continues to press on the copper until the iron bar has come opposite the faces of the two magnets, which were thus charged with magnetism. On its coming into that position, the current is cut off from these two magnets, by the wire or rod of copper passing from the copper to the wood, and thereby breaking the connexion with the battery. But when the wire or rod of copper leaves the copper on the one cylinder, it leaves the wood, and passes to the copper on the other cylinder at the other end of the axle, and in so doing connects the other two magnets with the battery, and they pull the next iron bar in the same manner. At the other end of the carriage there are other four magnets and wooden cylinder, with iron bars arranged in the same manner.

The battery which is used for propelling the machine is composed of iron and zinc plates immersed in dilute sulphuric acid, the iron plates being fluted so as to expose greater surface in the same space. The weight propelled was about six tons.—*Edinburgh Evening Journal.*

IMPROVEMENT IN SHIP BUILDING FOR STEAM NAVIGATION.

A most ingenious model has fallen under our observation, of which Captain Drew (the destroyer of the piratical *Caroline*) is the inventor, for strengthening ships of war, so as to make it all but impossible they shall become hoggish. To steam-vessels of the larger class the adoption of this simple and comparatively inexpensive machinery will prove of most vital importance. The immense weight of the engines requisite for a steam-ship render her more than ordinarily liable to break amidships. Captain Drew's plan was, we are told, suggested by the ingenious and admirably effective operation lately performed on the *Penelope*.

The grand feature of his project is to relieve a steam-vessel from the vast weight of machinery amidships, and to throw it upon two distant parts of the ship, much more capable of sustaining it; and if there be any one vessel to which such an adjunct will be more especially necessary than another, it is the *Penelope*, whose machinery will be placed exactly in the space occupied by the 60 ft. of timber which remains to be added to its length. Captain Drew's plan consists of two longitudinal pieces of timber firmly trussed together, constructed on something like the principle of the arch of a bridge, which will be capable of bearing an immense weight. These bearers are to be covered by a platform for the machinery of four-inch plank; so that the strongest part of the vessel will, in future, be that which has hitherto proved the weakest. It is well known that the unfortunate *President* was broken-backed before she left the British Channel on her last trip, from the immense weight of her machinery amidships—the undoubted cause of her melancholy catastrophe. The owners of the British Queen are, we are told, about to cut her into two, for the purpose of avoiding a similar catastrophe. And it is well known that the long steam-vessels running in Canada seldom last more than 5 or 6 years, from the same cause. If, therefore, Captain Drew's plan should realize the expectations we have formed of it, it cannot fail of proving of most vital importance to the navy at large, and to steam-ships in particular.

We had almost forgotten to notice another important advantage that will

be gained by Captain Drew's plan. The circumstance of the machinery being placed upon a platform that will be, to a certain extent, elastic, will obviate in a great degree that constant jar which is so trying to the timbers of a steam-ship, and so inconvenient to its occupants.

We have the greatest pleasure in speaking of this invention as we think it deserves, inasmuch as we have understood that Captain Drew has no interested motives in placing it before the public. He seeks no patent, and desires no reward beyond the credit of being instrumental in preserving not only valuable property, but human life, from destruction.—*United Service Gazette.*

STEAM NAVIGATION.

The launch of the "*Prince Albert*" Iron Steam Ship took place on Friday, the 30th Sept., at Mr. Coutts's yard, at Newcastle. The following are her proportions:—Length between perpendiculars 155 ft., length over all 180 ft., main breadth 19 ft. 6 in., depth of hold 9 ft. 6 in., draught of water when light with machinery 3 ft. 6 in., and when loaded with passengers 4 ft. 6 in. The ribs or frames of this vessel are formed of angle iron, 4 in. broad on the web, placed 2 ft. apart, and the thickness of her plates are three-eighths, five-sixteenths, and one-fourth in. respectively. She has four longitudinal keelsons 14 in. deep, 3 in. thick, with 8 cross keelsons of the same size of plate; the whole of these keelsons have strong angle iron fixed on their upper edge and riveted to the ribs and plates of the vessel, thus forming the bottom into a level platform of great strength, on which the engines and boilers are placed. There are other parts of the *Prince Albert* novel in their construction, such as the iron deck beams and gunwhale stringer, the former is formed of plate 1 in. thick and 8 or 9 in. deep, with a piece of angle iron on each side to which the deck deals are attached by screw bolts; these beams form a diagonal knee at the sides of the vessel, and are attached to every alternate rib, forming one of the strongest and lightest beams yet constructed. The iron gunwhale stringer is formed of plate 3 in. thick, and from 9 to 11 in. broad, with a flange turned downwards, and covering the plates of the vessel to which it is riveted, and another flange on its inner edge, turned upwards and let into the waterway or covering board; this stringer is fixed down to the ribs and beams of the boat, and will form one continuous horizontal knee from stem to stern. The covering board is of pitch pine, 3 in. thick and 14 in. broad, bolted down to the gunwhale stringer, and forming with it a very strong protection from accidents or damage by collision with vessels or otherwise. The deck deals are only 4 in. wide, and are tongued with iron hoop let in, with white lead in the grooves so as to preclude the necessity of caulking or pitching the joints. There are two iron water-tight bulk-heads, forming the vessel into three distinct compartments. The lines or model of the boat are considered by judges to be laid down on the most scientific principles; and altogether she forms one of the finest specimens of scientific skill and mechanical arrangement of marine architecture that we have witnessed. And should her machinery prove equally complete and efficient, which, from the manner Mr. Coutts speaks of it, we believe will be the case, the *Prince Albert* will be one of the fastest boats yet started on the Thames. The *Prince Albert* will be towed to London to receive the engines which are made by the owners, Messrs. Braithwaite, Milner & Co. The boilers are of Spiller's patent tubular, somewhat like locomotive boilers, with this difference, that the water circulates through the tubes instead of the fire. They were made and put on board the boat here by Mr. Coutts, and are said to be capable of generating sufficient steam for 130 to 140 H. P. in a space of about 7 ft. in the length of the vessel.—*Newcastle Paper.*

Naval Experiments on the Defences of Steam Boilers.—A highly interesting experiment was tried at Portsmouth last month, on board the Excellent gunnery-ship, Captain Sir Thomas Hastings, to test the efficacy of the defences of the boilers in steam-ships of war. One of the greatest difficulties to surmount, in order to render the steam navy of greater efficiency in action, is to afford adequate protection to the boilers against the shot of the enemy, as a ball perforating them would at once place the vessel *hors de combat*. With the view of affording this protection to the boilers, several war steamers have been fitted up with extra defences at the parts where the boilers are fixed. These defences consist of 16 plates or layers of metal, each 3/4 inch thick. The object of the experiment on board the Excellent was to ascertain what resistance these defences of boilers would offer to a cannonade at point blank distance, which is 400 yards. An iron target was prepared, made exactly of the material which constitutes the protection of the boilers of a steamer, and placed at the distance of 400 yards from the ship, from which guns at different calibres were fired at it. Admirals Sir E. Codrington and Parker, and a great number of naval officers, including those from the Austrian frigate, were present to witness the experiment. The first shot that was fired was an eight-inch hollow shot, and was projected from a 68-pounder, medium gun. It struck the bull's-eye, or centre of the target, and, slightly indenting it to the depth of about 5 in., rebounded therefrom, and was split into several pieces by the concussion. The second shot was a solid 32-pounder, and was fired from a gun of 9 ft. 6 in.; it struck the edge of the target, glanced off, and was split into two pieces. The third shot hit the centre of the target, where it lodged, having penetrated several plates. The fourth shot struck the third, and sent it clean through all parts of the iron, splitting it into numberless pieces, which were found on the off-side of the wooden stage on which the target was fixed. The fifth and sixth shots went through the perforation made by the third and fourth. About 10 other shots were fired, all striking the target in various parts, and completely destroying it. The result of this experiment has shown how totally inadequate are the present defences of the boilers of war steamers to protect them from the assaults of the enemy where a precision of fire had been attained.—*Times.*

Sale of the Great Western Steam Ship.—On Monday afternoon, the 11th October, at two o'clock, the steam ship *Great Western* was offered for sale

by public auction in Bristol. The bidding was very spirited, but she was ultimately bought in at £40,000.

Royal Navy.—The launch of the "Cumberland" 70-gun ship took place last month on the anniversary of the glorious victory of Trafalgar, at Chatham dockyard. Her dimensions are as follows:—Length on gun-deck, 180 ft.; for tonnage, 143 ft. 5½ in.; extreme breadth, 54 ft. 3 in.; for tonnage, 53 ft. 6 in.; moulded, 52 ft. 9 in.; depth in hold, 22 ft. 4 in. Her tonnage is as follows—burden by the old rule, 2,244 tons 40 lb.; new rule, 2,055 tons 88 lb. Her armament—lower-deck, 4 guns, 8 in. in diameter, 65 cwt., length 9 ft.; ditto, 22 guns, 32-pounders, 56 cwt., length 9 ft. 6 in.; middle-deck, 2 guns, 8 in. in diameter, 65 cwt., length 9 ft.; ditto, 26 guns, 32-pounders, 50 cwt., length 9 ft.; quarter-deck, 16 guns, 32-pounders, 39 cwt., length 7 ft. 6 in., and poop. The light draught of water of the Cumberland is, afore, 13 ft. 4 in., and abaft, 17 ft. 9 in. She broke (as it is technically termed) in launching 1½ in. She is not a particularly elegant craft, but is well calculated for the shallow water of the north seas.

MISCELLANEA.

Remedy for Broken Axles.—M. Huan submitted to the Academy of Sciences his invention for preventing accidents on railways by the breaking of the axle, which consists of a modification of the wheel of the locomotive, that if the axle should break, the wheel itself becomes an axle! and prevents further accident.

Electricity of Whirlwinds.—M. Arago, in allusion to the opinion expressed by several persons on this subject mentioned to the Académie des Sciences, some observations, made by M. Hortola on a storm, on the 24th ult., in the department of the Aude. This gentleman relates that on the occasion referred to, the iron bars of windows, the gutters of sheet iron, the plates of insurance companies, and other metallic objects were carried away by the whirlwind, thus indicating the presence of electricity.

Oscillatory Movement of the Sea.—The Academy of Sciences of Naples having charged M. A. Nobili to inquire into the circumstances connected with the oscillatory movement of the sea in the Gulph of Naples, it appears that he has studied the variations of the mean level according to the direction of the wind, and has found that the greatest elevation of the mean level takes place in the west-south-west winds, and the smallest in those of the north-north-east. This is also the case on the western coast of Sicily. M. Chazallon has also taken some observations on the tide at Toulon, from which it results, that the full tide of the evening is much higher than that of the morning.

Improved Fowling-piece.—M. Matthieu, a Frenchman, has invented a gun which, immediately after it is discharged, recocks itself, and a new charge is conveyed in the direction of the barrel. This is repeated five or six times, and with such rapidity, that the gun can be discharged five times in three seconds. If the sportsman does not wish to fire with this rapidity, he can stop the action, and wait any time he pleases between each discharge. The combinations of the mechanism are such as to prevent accidental explosion. This invention is not new. Baron Heurteloup, more than two years ago, produced a fowling-piece and a musket on this principle, and, according to report, he has made such improvements that double the number of charges of M. Matthieu's gun may be fired in almost the same space of time.

The Galvano-plastic Process.—A proposition has been made by M. Corney to employ this process after embalmment, for the preservation of the human body after death. The idea, however extravagant it may appear, is said not to be original, and that beautiful specimens are to be seen of small animals, birds, insects, &c. which have been thus preserved by M. Soyer, of the Place Vendôme.

The Green Park.—The site of the house and grounds of the late ranger has been levelled, new foot-paths laid out, and the whole thrown into the park, and it is now open to the public. The projected widening of Piccadilly from Devonshire House to Hyde Park Corner, is deferred for the present, as an act of parliament is said to be required.

St. Paul's Cathedral. which has been closed for some months, has been thoroughly cleaned, and is now re-opened. The old oak panellings and carvings of the choir have been varnished, the seats and pulpit covered with new cloth, the monuments purified, and the interior generally cleared of the accumulated soot and dust of years, so that the whole has a comparatively cheerful appearance.

The Artesian Well at Grenelle.—The new tube is now completed to the surface. M. Arago is of opinion that when the tube, beyond the opening of the well, shall have been carried to the proposed height of 33 metres, (108 feet), and the force of the rush of water have been thus diminished, it will become quite clear. It appears that the new tube, which has been introduced into the well, does not reach to the bottom; a portion of the former tube, which could not be extracted, has forced its way transversely, and prevented the end of the new tube from penetrating as far as was intended.

Mr. Jeffrey's Cement.—Some further experiments have been made in the marshes at Woolwich. A block of wood submitted by Mr. Jeffrey was bored to the centre, exactly in the middle of the joining, and a 5½ inch shell inserted, for the purpose of tearing it to pieces. On a port-fire being ignited, the shell soon exploded, tearing the solid wood in all directions, and into numerous fragments, but in no part separating the pieces where the joining with the cement was made.

Caoutchouc Cement.—M. Vallé, a colour maker, observing the injury caused to the works of some of the greatest masters by the influence of the atmosphere upon the canvas, has invented a solution (said to be of caoutchouc) which, although applied to both sides of the canvas, leaves it sufficiently

elastic to prevent cracking, and secures it against the action of the atmosphere. To this he adds a peculiar kind of varnish for the painting, which is said to defy the ravages of time.

Survey of the Skies.—A survey of the skies was made on Monday, the 11th inst. in all parts of the kingdom, on a plan arranged at the last meeting of the British Royal Society of Agriculture, for the purpose of ascertaining the form and position of the clouds in the morning, at noon, and in the evening, together with a great variety of other facts respecting the force and direction of the wind, the state of the thermometer and barometer, and other meteorological appearances and phenomena. The object of this extensive survey was to collect facts respecting the weather, for the guidance of practical agriculturists.—*Globe*.

National Museum of Artillery, Madrid.—This museum has been removed to the Palace of Buen Retiro. It is now under the active direction of Don Leon Gil de Palacios, a distinguished artist and antiquary. The wrought iron cannon made by the Carlists in Biscay are described as of great merit. Some ancient cannon from Andalusia are to be added. Among the objects of curiosity are the armour of Garcia Paredes, the lance of the Empecinado, the sabre of Torrigos, the knife of Manzanares, the uniform of Morelas, the founder of American independence, and the lance of Leon. It has been suggested that the Museum of the engineers and the Royal Armory be united to the Museum of Artillery.

Electrical Experiment.—In the course of experiments instituted by Messrs. Wright and Bain for the improvement of their electrical telegraph, they discovered that the electric circuit of a galvanic battery is as effectually completed through a large body of water as through an insulated wire. They have applied this curious discovery so effectually as to be now able to dispense with two of the wires heretofore thought necessary for the action of their printing telegraph; and they are thus enabled to print all communications, either verbal or symbolical, at any distance, by the use of a single wire. We understand they are now in treaty with the government to construct a telegraph on this principle between the admiralty and Portsmouth. One insulated wire would be laid down between the two points, to connect the galvanic battery of the outpost with the printing apparatus of the Admiralty, and the return current would be sent through the earth, in lieu of using a second wire to complete the circuit. Should the moisture in the ground not prove sufficient to conduct the electricity, the inventors propose to transmit the return current by water; making it pass down the Thames to the German Ocean, and thence along the Channel to Portsmouth; this roundabout voyage to be performed instantaneously. By thus simplifying, and consequently greatly reducing the cost of the electrical printing telegraph, the inventors have gone far towards rendering it generally available; another step in advance will dispense with all metallic connexion whatever.—*Spectator*.

Extraordinary Excavator.—"Yankee Geologist."—The following is a description of the wonderful machine, called the "Yankee Geologist," which has recently obtained great celebrity in the United States, for performances, which, for their extraordinary nature, and the peculiar manner in which they are described, will give them almost an air of romance; but, nevertheless, having reason to believe the "Yankee Geologist" to be an extraordinary invention, and capable of astonishing deeds, if not of all that is here set forth, I consider a notice of it sufficiently interesting to be deserving a place in your columns:—"We paid a flying visit on Saturday last to Otis' steam-excavator, in Brooklyn, where it is at work digging down the hill formerly known as Fort Green, and filling up the shallow inlet and quagmire, entitled the Wallabout, or so much of it as lies above the old road to Flushing. The 'Yankee Geologist' is surely a great curiosity. He walks right into a mountain as though it were a plate of hot cakes, and dips up a cartload at a shovelful, as fast as you please. He cuts right and left a path some six rods wide through a hill, and then takes a new swath. He is locomotive, and advances by his own steam-power, whenever the earth has receded before him, grades and stakes down for himself, and only requires one man to shovel and another to look after the fire and engine, though one or two others are generally required to smooth the track before him, &c., besides tending the carts, which approach to be filled on one rail track, and go off loaded by another. If he comes to a stone weighing only a ton, or such a matter, the 'Geologist' makes no bones of it, but pitches it into the cart like a peck of gravel; if he comes to a stone weighing some 4 or 5 tons, he takes him up more carefully, and lays him out on the side of his path. All this is effected by an immense shovel with a sliding bottom, at the end of an immense and complicated arm, worked by much ingenious and novel machinery. The inventor is now dead; the company have spent 30,000 dollars upon the invention before the first machine was made, and much more afterwards. The patent, which is now secured throughout Europe, is probably worth 1,000,000 dollars. An excavator complete costs about 6000 dollars, and will dig and load 1000 cubic yards of earth per day—equal to the labour of 150 men.—*Mining Journal*.

The Manufacture of Watches by Machinery.—A gentleman, who has devoted 20 years of his life to the subject, has made a variety of machines by which an incredible number of watches, of every variety of size, may be made in a day. By one of the machines 300 perfect plates can be produced in a day, by another the same quantity of barrels; by five machines the requisite number of centre, third, and fourth wheels (crossed, polished, and cut) with balances for 300 movements. By another 200 pinions can be cut and rounded; by another the holes are drilled, the tapping, the screw-holes, the various parts in the plate are sunk, planting the depths and escapement, &c., and all with such exactness as cannot be excelled, another for the making and polishing of pivots, &c. Four other machines will be sufficient for making pivots for 50 movements a-day; and to add to these, there are 20 other machines for every description of work connected with the watch-making, and which altogether constitute a set. The inventor has submitted these machines to be scrutinizing inspection of the most experienced makers of chronometers and watches in London, and not one has expressed a doubt of the work so reduced being incomparably superior to that done in the usual way. Among

other distinguished names in the trade we have observed those of Mr. Barwise, Mr. Barnshaw, Mr. Hewett, Mr. Vieyres, Messrs. Frodsham and Co., with about a hundred watchmakers in the country, who, with the Duke of Hamilton and Mr. Howell (of the firm of Howell and James) at their head, are engaged in carrying out the great and national object of restoring this lost and important manufacture to England by means that while they greatly lessen the price, will improve the quality, and entirely undersell our foreign rivals, and be very largely profitable to all parties concerned.

Astronomical Phenomena.—Mr. Glaisher, of the Cambridge Observatory, reports the following remarkable appearance on the 4th October:—"At midnight the sky had become perfectly clear and the air frosty. At 21 minutes after twelve I was much startled by what seemed to be a vivid flash of lighting, but on turning to discover its direction I saw a bright streak of light in Orion, about 20° in length at the moment of discovery; its centre was as bright as Jupiter, and the light plainly emanated from it in quick flickering waves on each side simultaneously, and at each wave the length and brightness decreased. This part of the phenomenon lasted 10 seconds; I therefore had time to recover my surprise and perceive the working of it. When the waving ceased there appeared to be a bright star in the place where I had seen the centre line of the streak, but whilst considering what star it could be, that I might note with accuracy the place of the phenomenon, I perceived that it gradually faded, and in the course of about two minutes it entirely disappeared, having, unlike the generality of meteors, maintained the same position all this time. The line of direction of the streak made, with Orion's belt to the south-east, an angle of about 40°, the centre light being 3° north of the upper star of the belt, and in the same straight line with the three stars in it. I hope this very singular meteor may have been observed by others, that this account of it may be verified."—*Norwich Mercury*.

Astronomical Clock at Strasburg.—An astronomical clock of remarkable ingenuity has lately been constructed at Strasburg by a M. Schwilgué. It is composed of three parts, respectively indicating the time of the day, the day of the month and year, and the movements of the constellations. The central moving power, which is another and very exact timepiece, shows on the face the hour and its subdivisions, strikes the hours and the quarters, and puts in motion several curious allegorical figures. The cock-crow, which had been mute since 1789, has been reproduced, and a procession of the apostles takes place daily at noon. The calendar shows the months, the days, and the dominical letter, as well as the Catholic calendar, showing every Saint's day in the year. The plate or face on which these figures and signs appear makes one revolution in 365 days for the common, and 366 for the 'bissexile' year, always reproducing the irregularity which takes place three times in every four secular years. The moving fasts and feasts are shown by an extremely ingenious process. On the 31st of December, at midnight, Easter day and the other moving feasts for the year appear on the calendar. The third division is the triumph of the artist's skill. A complete orrery after the Copernican system is produced. The movements of all the planets visible to the naked eye are represented. The earth is shown accompanied by her satellite, the moon, which accomplishes her revolution in one month. The different phases of the moon are represented on a different and separate globe. Another globe represents the apparent movement of the heavens, making one revolution in the sidereal day. This movement is subjected to that almost imperceptible power, known by the name of the procession of the equinoxes. The mechanism, besides many other things, shows the apparent movements of the sun and moon with wonderful precision, and for an indefinite period, so that the rising and setting of the sun, its passage to the meridian, the eclipses of the sun and moon, &c., are all represented on the face of the apparent time in a most ingenious manner.

Dredge's Suspension Bridge.—A new iron suspension bridge on Mr. Dredge's principle has just been completed, at Wraybury, in Buckinghamshire, about 20 miles west of London. It is stated to be a very light and powerful structure, and is not half so expensive as is the timber centreing for a common stone bridge of the same magnitude. It is 17 ft. wide, 100 ft. span, and is intended for every description of traffic. It is perfectly level from end to end. It was completed in three weeks after the foundation stone was laid.

The New River Head.—A number of labourers have been employed for some days past in cleansing the immense reservoir belonging to the New River Company, in Claremont Square, Pentonville. The sediment has been allowed to accumulate for 11 years, until at length the present measure became necessary. In some places there are 11 ft. of mud.—*Times*.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 29TH SEPTEMBER TO 27TH OCTOBER, 1842.

Six Months allowed for Enrolment, unless otherwise expressed.

EDWARD BELL, of the College of Civil Engineers, Putney, professor of practical mechanics, for "improvements in applying heat in the manufacture of artificial fuel, which improvements are applicable to the preparation of asphalt, and for other purposes."—Sealed September 29.

SAMUEL HENSON, of New City Chambers, Bishopsgate-street, engineer, for "improvements in locomotive apparatus, and in machinery for conveying letters, goods, and passengers, from place to place through the air, part of which improvements are applicable to locomotive and other machinery to be used on water or on land."—Sep. 29.

WILLIAM SMITH, of Grosvenor-street, Camberwell, gentleman, for "improvements in treating certain animal matters, to obtain products applicable to the manufacture of candles, and other purposes."—Sep. 29.

JOHN RAND, of Howland-street, Fitzroy-square, artist, for "improvements in making and closing metallic collapsible vessels."—Sep. 29.

JAMES HYDE, of Duckenfield, Cheshire, machine-maker, and JOHN HYDE,

of the same place, cotton-spinner, and manufacturer, for "an improvement or improvements in the machinery used for preparing cotton, wool, silk, flax, and similar fibrous materials for spinning."—Sep. 29.

JOHN RIBSDALE, of Leeds, for "improvements in preparing fibrous materials for weaving, and in sizing warps."—Sep. 29.

JOHN FRY WILKEY, of Mount Vernon, Exeter, commission agent, for "improvements in carriages."—Sep. 29.

JOHN GEORGE SHIPLEY, of Bruton-street, Berkeley-square, saddler, for "certain improvements in saddles."—Oct. 6.

JOHN OLIVER YORK, of Upper Coleshill-street, Eaton-square, for "improvements in the manufacture of axles for railway wheels."—Oct. 8.

WILTON GEORGE TURNER, of Gateshead, Durham, doctor in philosophy, for "improvements in the manufacture of alum."—Oct. 8.

CLAUDE EDWARD DEUTSCHE, of Fricour's Hotel, St. Martin's-lane, gentleman, for "improvements in combining materials to be used for cementing purposes, and for preventing the passage of fluids, and also for forming or constructing articles from such compositions of materials."—Oct. 8.

SAMUEL DOTCHIN, of Myrtle-street, Hoxton, jeweller, for "improvements in paving, or covering, and constructing roads, ways, and other surfaces." (A communication.)—Oct. 13.

WILLIAM EDWARD NEWTON, of Chancery-lane, patent agent, for "certain improvements in the manufacture of artificial fuel." (A communication.)—Oct. 13.

CHARLES THOMAS HOLCOMBE, of Valentines, near Ilford, Essex, Esq., for "an improved mode of using certain materials as fuel; also an apparatus or method for collecting the smoke or soot arising from the combustion of such fuel; which apparatus or method is applicable to collecting the smoke or soot arising from the ordinary combustion of fuel, and also the application of the products arising from the combustion of the first mentioned materials, as a manure, and for other useful purposes."—Oct. 13.

ROBERT WILLIAM SIEVIER, of Henrietta-street, Cavendish-square, gentleman, for "certain improvements in looms for weaving, and in the mode or method of producing plain or figured goods or fabrics."—Oct. 13.

PETER KAGENBUSCH, of Lyth, in the county of York, dyer, for "certain improvements in the treatment of the alum rock, or schist, and in the manufacture and application of the products derived therefrom."—Oct. 13.

HENRY BROWN, of Selkirk, manufacturer, and THOMAS WALKER, of the same place, manufacturer, for "improvements on woollen carding engines."—Oct. 13.

THOMAS SEVILLE, of Royton, Lancaster, cotton spinner, for "certain improvements in machinery used in the preparing and spinning of cotton, flax, and other fibrous substances."—Oct. 20.

JAMES PALMER BUDD, of Ystalyfera Iron Works, Swansea, merchant, for "improvements in the manufacture of iron."—Oct. 20.

WILLIAM LONGMAID, of Plymouth, accountant, for "improvements in treating ores and other minerals, and in obtaining various products therefrom, certain parts of which improvements are applicable to the manufacture of alkali."—Oct. 20.

JAMES STATHAM, of West-street, St. Giles's, Venetian lock maker, for "improvements in the construction of locks, for Venetian blinds used in carriages."—Oct. 29.

GILBERT CLAUDE ALZARD, of Tichborne-street, gentleman, for "certain improvements in bread, biscuits, macaroni, vermicelli, and pastry, and the mode of making the same."—Oct. 20.

GEORGE HAZELDINE, of Lant-street, Southwark, coach manufacturer, for "certain improvements in omnibuses."—Oct. 27.

JAMES GARDNER, of Banbury, ironmonger, for "improvements in cutting hay, straw, and other vegetable matters for the food of animals."—Oct. 27.

JOHN MULLINS, of Battersea, surgeon, for "improvements in making oxides of metals in separating silver and other metals from their compounds, with other metals, and in making white lead, sugar of lead, and other salts of lead, and salts of other metals."—Oct. 27.

ROWLAND WILLIAMS, of Manchester, fustian shearer, for "certain improvements in machinery, or apparatus for raising, shearing, and finishing velvets, or other piled goods by power."—Oct. 27.

TO CORRESPONDENTS.

L. K.—We cannot inform him.

B.—Sometimes; if he will call at our office, he can consult the Editor.

W. Williams.—Address The Secretary of the Society of Arts, &c. Adelphi, London.

T. B.—Self-acting river valve.—A paper by Mr. Haydon on the Schools of Design.—Notice of Mr. Shuttleworth's Hydraulic Railway.—F. W. S.—Improvement in the process of Sugar-making—will appear next month.

O. T.—We have received his last communication on Railway Curves.

Mr. James Whites' "elastic friction driver" in the Mech. Mag. No. 1002, Oct. 22, is a decided infringement on Mr. Trewhitt's patent, described in the Journal for last February and April.

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant, addressed to the Editor, No. 10, Fludyer Street, Whitehall.

No. 2 has been reprinted and may now be had of the Publishers.

Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume.

SCOTSWOOD SUSPENSION BRIDGE OVER THE TYNE.

SCOTSWOOD SUSPENSION BRIDGE,

Erected over the Tyne, near Newcastle.—Engineer, JOHN GREEN.

(With an Engraving, Plate XVI.)

We are indebted for the accompanying drawing and description of the above bridge, to our valuable correspondent O. T. of Newcastle-upon-Tyne, who has favoured us with several practical papers of great utility, part of which have appeared in the *Journal*.

Scotswood Bridge is erected over the Tyne, in a very picturesque situation, 3 miles west of Newcastle; it was commenced in August 1829, and opened on 12th April 1831. The two suspension towers in design approach the Norman style of architecture, and have a very noble appearance when viewed from the water; they are, together with the land abutments, constructed of solid masonry. The distance between the points of suspension of the centre opening is 370 ft., the two half arcs 180 ft. span each, which with the two towers make a total length of 670 ft. There are four suspension chains, two on each side, one over the other; each chain is 742 ft. long, the chord line of the centre span 370 feet, and versed sine or deflection 26 ft. 6 in.; the links of the chains consist of four flat wrought iron bars 10 ft. long, 4 in. deep, and 1 in. thick, placed parallel to each other, terminated with an eye at each end, and coupled together with five wrought iron plates 5 in. deep in the centre, and 9 in. across the widest part, and 1 in. thick, connected by bolts 2½ in. diameter, with octagon nuts 4½ in. diameter and 2 in. thick; the bolt holes of the long links are 9 ft. 1½ in. from centre to centre (see Figs. 5, 6, and 7.) The links above the suspension towers have bars 7 in. deep and 1 in. thick and 20 in. long from centre to centre, and connecting plates 10½ in. long from centre to centre; the roadway is suspended by bars 1½ in. square to the centre coupling bar, which has a lug on the underside with an eye, through which and the forked end of the suspending bar passes a screw bolt; the lower end of the suspending bar is attached to a stirrup iron grasping each side of the longitudinal string piece, which is carried by the iron wedges, as shown in fig. 4. The suspension bars are alternately suspended to the upper and lower chains. Each bar was proved to 40 tons. The suspension towers are 78 ft. high from the bottom of the footings to the top, and at the base 42 ft. long by 20 ft. 6 in., and above 37 ft. by 16 ft. 6 in., the footings are surrounded with sheet piling. The roadway is 23 ft. broad, which is constructed of Memel timber placed 8 in. apart, the ends resting upon and bolted to the longitudinal string piece on each side, as shown in fig. 4, and the top overlaid with planks covered with a composition of tar and gravel.

The masonry was executed by Messrs. Welch and Son of Gateshead, and the ironwork by Messrs. Walker and Yates of Birmingham. The estimated expense was £12,900, but from unforeseen difficulties in the foundation requiring extra work both in masonry and cofferdam, the total expenditure was £15,000. At the completion of the bridge the committee for the construction, in order to testify their high approbation of the masterly manner in which Mr. Green discharged his duties as engineer, presented him with a handsome silver claret jug.

Greenhithe Pier.—On Monday, Oct. 31, the retired and beautiful village of Greenhithe assumed a most animated scene, upon the occasion of the opening of this Pier. On the arrival of the first steam-boat at the Pier, which conveyed several of the Directors and Shareholders of the Pier Company, they were received by a numerous assemblage of their friends.

The Pier is constructed of timber, and is remarkable for durability, chasteness, and elegance, and reflects great credit on Messrs. Birch, the engineers and designers,

CANDIDUS'S NOTE-BOOK.

FASCICULUS XLIII.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. "Barry's Book" seems likely to become a by-word, and many are now endeavouring to pick a leaf out of it, some with very fair success, others with none. Rarely can imitators discern the difference, wide as it is, between *manner* and *manner-ism*: they just catch hold of some of the more prominent characteristics of the former, and then apply them at hap-hazard and on all occasions. There is almost always something to betray that they do not enter into the spirit of what they evidently propose to themselves as a model. So long as they have some express model to go by, and adhere to that, they may get on well enough, but no sooner do they begin to deviate from it, than they render manifest how very different their own unguided taste is from that which they have assumed, but which sits upon them most awkwardly and ungainly. It may be said that Barry himself is but an imitator, and that most of his ideas may be traced to direct authorities for them. Still, if this may seem to detract from him in some degree as an inventor, it also shows how very differently from his predecessors he looked at Italian architecture. How happens it that that particular mode which he introduced, and has brought into vogue, should, till then, hardly have been known in this country? The same sources from which he derived his taste had been open to others for at least two centuries, without their benefitting by them, or being able to perceive their value. Neither has he followed his models implicitly, even where he is most open to the charge of direct imitation: on the contrary, he has discriminated between their beauties and their defects, of which latter some are glaring enough, even in works that are stamped by no ordinary merits. Those singular inequalities of taste which mar or disfigure some of the finest, and what may be called the purest, examples of the Italian style, he has happily avoided, giving us, as it were, the very cream of that style. It has been remarked before now—probably by myself also—that one very great, and, I am sorry to say, uncommon merit in Barry's designs is, that they are all of a piece, and all carefully finished up. In others there may be very happy ideas, and great merits in parts; but then it is generally only in parts, and in many instances the faults preponderate over the beauties; at least neutralize them, jarring most harshly, like so many false notes in music.

II. Mr. Barry's example and that of others, who, in re-adopting Italian architecture, have gone to what may be distinguished by the name of the Ante-Palladian style, may be taken as a tacit confession on their part, that the Palladian itself is greatly inferior to the other; and however disposed they may be to join with those who cry up the Palladian school—for the sake, perhaps, of quietness—their practice unequivocally condemns it. Independently of its intrinsic merit, one thing which at present recommends the species of Italian introduced among us is its novelty; but as that attraction can be of no very long duration, it could be wished that an attempt were made to throw more variety into it, instead of invariably aiming at the same or nearly the same character, not only as regards the general mass, but also the individual features and members. The same style would admit of great diversity of treatment in regard to windows, a source of variety all the more worth being turned to as much account as possible, because little scope for variety is afforded in regard to the general composition. Fortunately, Barry himself has furnished me with an illustration of what I could wish to see pursued and carried much further,—in the south façade of the Travellers' Club-house, where the windows are of more ornate character and more original design than usual, and the whole is more playful, yet the style is not at all violated; its breadth and repose are preserved, and there is simplicity combined with richness, and what is more, that richness is combined with gracefulness. That front is also a happy instance of what may be done by merely having recourse to rustication as a means of embellishment.

III. In continuation of the remarks on the style above spoken of, one thing that is not to be lost sight of is, that justice cannot be done to it, nor its character kept up even tolerably well, if the proportions be neglected—proportions all the more deserving of notice, because little mention is made of them, and little attention paid to them; namely, the proportion of solid wall to the apertures, both as regards breadth of piers between windows, and breadth of horizontal surface between the separate floors and their windows. If sufficient space cannot be allowed for these proportions, very much that is essential to character is forfeited, although the composition and all its details may be just the same as where the due proportions are observed. All grandeur of manner is lost, and is replaced by a certain littleness and offensive "squeeziness,"—a term, by the bye, that may very well be allowed to pass current, as it is sufficiently expressive; nor is exception to be taken to it, when the fault itself which it describes is tolerated much more than it ought to be. It is this "squeeziness," among other things, that causes those long slips ycleped Terraces, in the Regent's Park, to look like so many barracks flashily bedizen'd out with all sorts of Brummagem architectural finery—sham pediments, columns, (crammed in between windows) pilasters, fluted in order to make amends for hole-in-the-wall doors, and here and there a painted sham window—to say nothing of garrets peeping over balustrades, and chevaux-de-frize of chimneys, bristling like so many porcupines on the roofs. Compare Chester or Cumberland Terrace with the Reform Club-house; the first are all bloated littleness, made up of would-be finery, and without the least refinement. On looking at them, you long to block up every other window, to take away their columns and starved entablatures, and to give them a cornice where a cornice ought to be, above and not below the uppermost windows.

IV. If a memorial of nothing else, the column in—or rather poked out of—Trafalgar Square, will serve to keep in recollection the extraordinary fact, that after two competitions, and from among nearly 200 designs, some of them by our chief architects and sculptors, no greater effort of genius could be selected, nothing better worthy of being carried into execution, than the hackneyed common-place idea of a huge column, which any one who can draw can design. It will now stand as a monument either of the utter incompetence of British artists to accomplish anything superior, or of the utter incompetence of the Committee to form any opinion; and of their sulky obstinacy in persisting to adhere to their unfortunate choice, after the extreme dissatisfaction expressed at it, and after they had actually held out the hope of abandoning it, by allowing a second competition to take place, thereby affording themselves an opportunity for correcting their former mistake. Far more creditable, because far less impudent, would it have been on the part of the committee, to have at once refused all further competition, contenting themselves with disappointing our expectations once. If they were determined to stick up a long pole, there was at least no occasion to make of it two *bauks*. One baulk was quite enough, in all reason; the second might, in decency, have been spared us. The only excuse is that they seem to have taken Nelson's own motto for their guidance, but construed it most unluckily, supposing "*Palmas qui meruit, &c.*" to mean "Anything may be *palmed* upon poor John Bull." They may have honoured Nelson, though very equivocally, but they have most unequivocally disgraced themselves by erecting what will be an object of contempt and derision to all persons of taste.

V. Common as it is, it is a very lame and shuffling excuse when those who profess to give us historical and critical remarks on architecture, break off as soon as they approach their own period, under the pretence of being restrained by "delicacy" from speaking of their contemporaries. In most cases the real truth would be, that they have no opinions of their own to offer, and can get no ready-made ones out of books, as they can respecting persons and things that have been spoken of repeatedly. A nice man, Swift has told us, is a man of nasty ideas; and so, in the delicacy of these over-scrupulous writers, there is something the reverse of complimentary. The inference to be drawn from their silence is, that were they to offer any opinions at all, they would be highly prejudicial and offensive ones. They are

too good natured to censure, and are by far too scrupulous to commend, against their critical conscience. Delicate souls! but then why do they meddle with what requires a firmness of purpose which they do not possess? why do they undertake an office so highly disagreeable to their feelings, and so much at variance with their notions of propriety and discretion?

VI. I have often observed that those who affect to attach little or no importance to "matters of mere taste," are apt to be excessively sore if you venture to find fault with their own taste. After telling you that what they have done makes no pretensions to merit of design in any respect, after assuring you that there is nothing to admire in it, such persons will look confoundedly nettled at you if you point out faults that might easily have been avoided. While with mock humility they disclaim your admiration, they not only expect you to express it, but are sulky if you do not. While they profess to have built merely to please themselves, they are angry if every one else does not profess to be equally well pleased also. I well remember one captious individual of the kind, who was so excessively indignant at some comments on the taste shown in the front of his house, which had a large bird-cage-looking viranda on Ionic columns, that he blustered most terribly, and talked of bringing his action against the publisher of the periodical wherein they had appeared! Most unquestionably every one who builds has a right to please himself—to erect a row of brickbat battlements on the top of a cockney-looking sash-windowed house, and call it a castle; or to commit any other absurdity. Yet while he in that manner avails himself of the *Mæus* side of the privilege, let him not forget the *Tuum* one, but bear in mind that people are just as much privileged to laugh at him, as he is to make a fool of himself, and have just as much right to ridicule his bad taste as he has to display it.

VII. Not much dependence is to be put upon Nagler's "*Künstler-Lexicon*;" at least not for its notices of English artists. The article on the late Augustus Pugin, is little more than a tissue of blunders from beginning to end. Although he died at the end of 1832, he is spoken of as still living; and although he was about 63 at that time, he is said to have been born in 1780, and to have been a native of London! For a long time, we are told, he devoted his attention to the public buildings of the English metropolis, before he began to direct it to the study of Gothic architecture, travelling through his native country for that purpose! In the year 1839, it seems, he began the Roman Catholic church at Manchester, one of the finest specimens of Gothic in this country! It is a pity that Nagler did not mention the "*Contrasts*" as one of his publications; more especially as he has not scrupled to attribute to him the illustrations in Britton's *Cassiobury*—or as he spells it, *Castuobury*. Nagler, it is to be hoped, does not blunder quite so much by wholesale, in his notices of Continental artists, because he is perpetually quoted as the authority for articles of that kind, in the new "*Biographical Dictionary*."

VIII. Whatever the reviewers may say of Mr. Gwilt's new work, they will hardly accuse him of servile adulation to the powers that be! When speaking of palaces—instead of sliding in a graceful compliment to Windsor Castle as being the bright particular gem which redeems this country from the reproach of having no worthy abode for its sovereign, he damns it with faint praise, uttered in a very sneering tone. Windsor Castle, he gives us to understand, is very far from being a model for a palace, and that its attractions lie more in its site and scenery than in its architecture. He has taken care, however, that posterity shall not learn from him the name of the architect employed upon it, for no where does he mention Sir Jeffry Wyattville, whom he has excluded from his list of architects—as he has, likewise, James Wyatt, although he has given a place in it to some individuals of far less note. Of course the omission must have been intentional, since it is not for a moment to be supposed that either Mr. Gwilt or any one else at all acquainted with the history of modern English architecture, should not know of, or forget, such persons. Surely James Wyatt might have been admitted into the company of Isaac Ware and James Payne, neither of whom were very brilliant luminaries in the art; although the first of them edited *Pal-*

Ladio—a very great merit indeed in Mr. Gwilt's eyes. Whatever his real abilities, Wyatt was incontestibly a celebrated architect, and entitled to notice, if only as forming an epoch in the art, by being the first to revive in practice, with any tolerable success, the pointed style. If such omissions are to be understood as tacit condemnations of the parties so excluded, they are not on that account the more warrantable. Mr. Gwilt holds his St. Peter's keys rather too tightly; since he passes over the name of Borromini in his list of architects, he would probably exclude that of Cromwell from a history of England, or Nero from that of Rome. Were biographical works to be drawn up on the same principle of exclusiveness, were the names of only the pre-eminently great and worthy to be admitted into them, the 70 volumes of the *Biographie Universelle*, would shrink down to seven. After seeing Mr. Gwilt's *Paradiso*, we should like to take a peep at his *Inferno*; and as we do not meet with Cagnola, Schinkel, Wilkins and Wyattville in the former place, we shall, no doubt, find them stowed away in the latter.

THE ECCLESIASTICAL COMMISSION AND THE ARCHITECTURAL SOCIETIES.

OUR present number affords much matter for meditation, and particularly to those who think these are times to set the public and the march of intellect at defiance. To the unprejudiced observer it will be pretty evident, that if the architects neglect their public duty, there are others who will do it for them. The profession must, therefore, be up and stirring, or the Architectural Societies will play the *Maitres du Palais* to their *fainéantisme*. While the Royal Institute of British Architects can scarcely find matter for its papers or for its transactions, or any thing to do, *lay architectural societies* are springing up over the country, which find plenty to do, and seriously threaten the prerogatives of architects. With the progress of these societies we are much pleased; they are a good sign of the times, they promise to educate the public, to employ the architect, and to preserve our ancient monuments. But here we must stop—we cannot allow the societies to be supreme judges of architectural merit and the dispensers of patronage; we think that they cannot become so without injury to the art and its professors: it must take away the responsibility from the architect and tend to patronize show instead of solidity. As an instance showing some of the fruits of the proposed system, we call attention to an advertisement from the Yorkshire Architectural Society in our present number, calling on architects to send in designs, without stating whether they are to receive either premium or employment. We also invite attention to the outrageous proceedings of the Ecclesiastical Commission, by which all the parsonage houses of the country are to be put under one architect; and the same stereotyped designs universally distributed. Now is the time, therefore, for the Institute to exert itself, to show regard in its proceedings, to defend manfully the rights of the profession, and to keep pace with the spirited exertions of the architectural societies.

DIRECT ACTION ENGINES.

As it has been our good fortune to have published drawings and descriptive letter-press of various engines of this class—the productions of some well known firms, it is now our intention to give an analysis of the same, as it relates to their general proportions and arrangements, strictly adhering to information derived from the published statements, making few comments, detailing facts, believing the same will be interesting to our readers. We began with Mr. Field's 2 cylinder engine in March 1840, Mr. Joseph Maudslay's annular engine followed in October 1841, which was succeeded by the *Virago* engine of Boulton and Watt, in its turn followed by the *Infernal's* engine of Miller and Co., ending with a design for a pair of engines by Borrie and Co. of Dundee. We now propose to analyze these in the order of their publication.

Mr. Field's double cylinder engine, published March 1840, p. 73, vol. 3.

Each cylinder 35 in. diameter and 3 ft. 9 in. stroke, regular speed say 26 strokes per minute, or 195 ft. Then
 $35 \text{ inches diameter} = 962.115 \text{ inches area} \times 2 = 1924.23 \text{ inches and}$
 $\frac{1924.23 \times 195 \times 7}{33000} = 79.593 \text{ horses for both cylinders, or in round}$

numbers, say 80 H.P., for which they were probably intended.

Piston Rods $3\frac{1}{2}$ in. diameter = 10.21 in. area, less than $\frac{1}{16}$ diameter of cylinder.

Connecting Rod $5\frac{1}{2}$ in. diameter = 23.75 in. area, a little more than both piston rods.

Air Pumps 24 in. diameter and 2 ft. 4 in. stroke. The area = $452 \times 28 \text{ in. stroke} = 12666 \text{ cubic inches contents, and the cubical contents of both cylinders, (area } 1924.23 \times 45 \text{ in. long)} = 86590.35 \text{ cubic inches} = 6.85 \text{ times the contents of air pumps.}$

Condenser 3 ft. 10 in. across, 1 ft. deep, by 7 ft. 6 in. long = 28 ft. 9 in., say with convexity of cylinder bottom = 30 ft. cube.

We have $\frac{30}{80} = .375$ of a foot per horse, or for air pump (contents = 7.318 cubic feet) $\frac{30}{7.318} = 4.1 \text{ times.}$

Shafts. Centre of shafts 12 ft. 6 in. above bottom of condenser, or top of vessels floor timbers, adapted to a ship of 8 ft. 3 in. draft, wheel being 16 ft. 3 in. diameter, $\times 5.3 \text{ long and } 21 \text{ in. breadth of paddle, necks } 9\frac{1}{2} \text{ in. diameter and } 8 \text{ in. long, same as annular engine.}$

Slide openings, or ports, $11\frac{1}{2} \text{ in. long} \times 3 \text{ in. wide for each cylinder} = 69 \text{ in. area. Slide valve round, } 15 \text{ in. diameter and } 7 \text{ in. motion.}$

Space required. Fore and aft = 10 ft. 9 in.

Over all athwart = 12 ft. 9 in.

or say a superficial space of = 132 feet.

Mr. Joseph Maudslay's annular engine, pub. Nov. 1841, p. 369, vol. 4.

Cylinder, 54 in. diameter = 2290 in. area, and diameter of internal tube = 25 in. = 491 in. area, and $2290 - 491 = 1799 \text{ in. the area of the working piston. Stroke } 4 \text{ ft.} = 200 \text{ ft. per minute at } 25 \text{ strokes. We have } \frac{1799 \times 200 \times 7 \text{ lb.}}{33000} = 75.3 \text{ H.P.}$

Piston Rods. Two in each cylinder, each = $3\frac{1}{2}$ in. diam. = 11.044 area $\times 2 = 22.088$ or $5\frac{1}{2}$ in. diam. if in one, rather less than $\frac{1}{16}$ diam. of cylinder.

Connecting Rod, = 5 in. diam. = 19.63 area, or less than both piston rods.

Shafts, necks $9\frac{1}{2}$ in. diam. by 8 in. long, same as in the two-cylinder engine.

Air Pumps, 26 in. diam. = 531 in. area $\times 2 \text{ ft. stroke} = 7.372 \text{ cubic ft. content. Cylinder } 12.5 \text{ ft. area} \times 4 \text{ ft. stroke} = 50 \text{ ft. cube contents, and } \frac{50}{7.372} = 6.75 \text{ times the air pump.}$

Condenser, (as near as can be obtained from drawing,) is 5 ft. $\times 6 \text{ ft. } 6 \text{ in.} \times 12 \text{ in.} = 32.5 \text{ cu. ft. content. Then } \frac{32.5}{76.3 \text{ H.P.}} = .125 \text{ of a foot per horse, or for air pumps } \frac{32.5}{7.372} = 4.4 \text{ times air pump.}$

Slide openings, 19 in. long by $3\frac{1}{2}$ in. wide = 66.5 in. area, or smaller in proportion than the two cylinder engine.

Space required, is fore and aft, 8 ft. 6 in.

Athwart, with 3 ft. passage between, 16 ft. 3 in.

Say a superficial space of 138 ft.

Virago Engine by Boulton, Watt and Co., pub. Feb. 1842, p. 55, vol. 5.

Cylinder, $64\frac{1}{2}$ in. diam. = 3292.8 in. area, 5 ft. stroke, and $21\frac{1}{2}$ strokes per minute, or 215 ft. = 150 horses each. Thus $\frac{3292.8 \times 7 \times 215}{33000} = 150 \text{ H.P.}$

Piston Rods, 6 in. diam. = 28.27 in. area, say about $\frac{1}{4}$ of cylinder's area.

Connecting Rods, 6½ in. diam. ends, and 7½ middle, say 6½ = 33.18 area, or about an $\frac{1}{2}$ more than piston rods.

Length of Rod, is 8 ft. 2 in. Shaft being 19 ft. 9 in. from top of floor timbers of ship.

Air pumps, section not shown on drawing, but appear to be 37 in. diam. = 7.466 ft. area $\times$ 2.5 stroke = 18.66 cubic ft. content per stroke.

Cylinders 64½ diam. = 22.70 ft. area $\times$ 5 ft. = 113.5 cu. ft. contents, and $\frac{113.5}{18.66}$ = six times the air pump.

Condensers, each engine separate, 10 ft. 10 long $\times$ 6 ft. 3 $\times$ 2 ft. 8 deep = 180 cu. ft., but deducting slides, air pumps, foot valves, &c., the content is 100 cu. ft., or 50 for each engine, or $\frac{1}{2}$ of a ft. per horse, and for air pump, $\frac{50.0}{18.66}$ = 3.7 times its contents.

Shafts are 11½ in. diam. at necks, and bearing 13 in. long, the centre, bearing a crank to work air pump, is 15 in. diam. by 6 in. long.

Slide Valves. Thoroughfares or ports, 5 in. $\times$ 24 in. = 120 in. area.

Hot Water Cistern, is 2 ft. 10 in. wide, 3 ft. 11 in. long, and 4 ft. 1 in. high, contents 45.3 cu. ft. less exhausting passages = 35.7 ft. true contents. Air pump contents 18.66 ft. we have $\frac{35.7}{18.66}$ = 1.92

times, say twice the contents of air pump.

Waste Water Pipes, 9 in. diam., the hot water cisterns acting as an air vessel.

Columns, wrought iron 7 in. diam. at bottom and 5 in. at top. Lower columns, cast iron, 10 in. diameter. Space occupied is 18.6 athwart, and 6.4 fore and aft, the width of cylinders. Air pumps being in centre line of ship, thus,

$$\begin{aligned} 18.6 \text{ by } 6.4 &= 117.2 \text{ sq. ft.} \\ \text{Air pumps } 4 \text{ ft. } 8 \text{ in. } \times 6.6 &= 30.4 \text{ "} \\ &= 147.6 \text{ sq. ft.} \end{aligned}$$

Mr. Joseph Miller's Direct Action Engine, published June 1842, p. 177, vol. 5.

Cylinder, 65 in. diam. (3318.31 in. area) 5 ft. stroke, 21½ strokes or 215 ft. per minute, power 151.33 horses.

$$\text{thus } \frac{3318.31 \times 7 \times 215}{33000} = 151.33 \times 2 = 302.66 \text{ H.P.}$$

Piston Rods, 6 in. diam. = 28.27 area, less than $\frac{1}{4}$ of cylinder.

Connecting Rods, 6½ in. diam. at end, and 7½ in. at middle, say 6½, = 33.18 in. area, or about $\frac{1}{2}$ more than piston rod. Length of rods, 8 ft. 6 in. Shaft, 19 ft. 6 in. from floor timbers.

Air Pumps, 30 in. diam., (706.86 in. area, or 4.90 ft.) and 2 ft. 6 in. stroke; 4.90 ft. $\times$ 2.5 = 12.25 cu. ft. contents. Cylinder = 23.04 sq. ft. $\times$ 5.0 = 115.20 c. ft. contents, and $\frac{115.20}{12.25}$ = 9.4 times the air pump.

Condenser, each engine separate, 3 ft. 2 in. wide $\times$ 2 ft. 6 in. fore and aft, and 4 ft. 6 in. high contents = 35 cu. ft. for each engine, and $\frac{35}{151}$ = .233 of a foot per horse, and $\frac{35}{12.25}$ = 2.85 times the contents of air pump.

Shafts (as far as drawing shows) are 12 in. diam. by 14 in. bearing.

Slide openings, 24 in. long, depth not shown, hollow slide, exhausting between the two faces, steam given at top and bottom.

Hot Water Cistern, 2 ft. 3 in. wide, 1 ft. 4 in. fore and aft by 1 ft. 8 in. deep. Contents = 5 cu. ft., or half air pump's content.

Waste Water Pipes, 12 inches diam. = 113 in. area, say $\frac{706}{113}$ = $\frac{1}{6.5}$ part of air pump's area.

Hot Water Pumps, 6 in. or 6½ in. diam. and about 21 in. stroke.

Columns of wrought iron, 5 in. diam. bolted to the top flange of cylinder, and not proceeding to their bases.

Space occupied is marked 8 ft. by 18 ft. 6 in., but over the feeding pumps and slides it measures 9 ft. 3 in., and athwart over the steam pipes and expansion valves it is 19 ft. 6 in., according to the dimensions marked 8 ft. $\times$ 18 ft. 6 in. = 148 ft. superficial.

Mr. Peter Borries Engines, Dundee, designed Nor. 1841, published July 1842, p. 213, vol. 5.

Cylinder 71 in. diam. (3959.2 in. area) and 5.6 stroke, 221½ ft. or 19½ strokes per minute = 186 horses each, or 372 H.P. for both engines, thus $\frac{3959.2 \times 7 \times 221.5}{33000}$ = 186 H.P. $\times$ 2 = 372 H.P.

Mr. Borrie calls the collective power of the two engines 352 H.P., at 210 ft. per minute, and 7lb. pressure; and further says, supposing pressure 8.5lb. and 210 ft. = 426 H.P. We suspect these data to be taken from the government contracts, probably coined at the Woolwich mint; as we prefer the authority of the late James Watt, we have followed his system, his proportions and pressure.

Piston Rods. 7 in. diam. or about $\frac{1}{4}$ the cylinder's diameter.

Connecting Rods, 7 in. diam. at end, and 9 in. in the middle, say 7 in. area = 38.48 or same as the piston rod.

Length of the Rod, is 8 ft. 4 in. only, shaft being 21 ft. 3 in. from floor.

Air Pump, is peculiar and novel in its application only, being Desagulier's double action pump, solid piston, valves and side pipes. Its diameter is 48 in. and 2 ft. stroke. We have 48 in. = 12.56 area

$\times$ 2 = 25.12 contents, and $\frac{151.195}{25.12}$ = $\frac{1}{4}$ contents of the cylinder.

Condenser, one for both engines, as well as one air pump; it is 7 ft. wide, by 7 ft. long, and 7.5 high = 367.5 total contents. Deducting air pipes and valves, &c., its true contents is 225 cu. ft., and $\frac{225}{372}$ = .60 of a foot per horse, and $\frac{225}{25.12}$ = 9 times the air pump, and $\frac{9}{2}$ = 4.5 times, supposing two air pumps, or one half to each engine.

Shafts, bearings are shown 15½ in. diam., and 22 in. long, or 1 to 1.4 of the diam., or about 3 in. larger in diam. than the proportions of the engines before detailed.

Slide Valves, are circular, 19 in. diam., ports 30 in. long, by 7 in. deep, = 225 in area.

Expansion Slides, are very simple and effective, its motion very small, and worked without noise.

Hot Water Cistern, is 12 in. fore and aft, 6 ft. high, and 4 ft. 6 in. wide, = 27.0 cu. ft., or for each engine = 13.5 cu. ft. or about half the air pump.

Waste Water Pipes, and hot water pipes, not clearly shown.

Columns, lower, of cast iron like *Virago* engine, and same diam. = 10 in., top part is a cast iron framing of tolerable design, heavy, though firm. We observe a good arrangement—the means of removing and replacing the steel strips in the cylinder guides, which soon wear from the great pressure. All engines of this class (with guides) should be so made.

Space occupied, is 10 ft. 6 in. from back of cylinder to face of expansion slide, and 12 ft. 3 in. over the steam pipes, and 22.6 from out to out transversely, being a rectangle of that size, or say 236.25 ft.

We have now analysed each of the five engines separately without drawing any comparison between them, or offering any comment or observation on their construction, or the adaptation of the direct action engines for vessels of the first rate class, such as are now being constructed by Government. Our only object for the present was simply to ascertain their relative proportions, and which we now propose to give in a tabular form.

¹ To be seen at the Southwark Water Works and St. Katharine's Docks; particularly the latter, there being six pumps of this description worked by two 80 horse engines, erected by Boulton and Watt in 1828.

TABLE OF PROPORTIONS OF DIRECT ACTION ENGINES.

	2-Cylinder Engine.	Annular Engine.	Virago.	Miller's.	Borrie's.

THE LIGHT OF ALL NATIONS.

In our *Journal* for October last, we gave a description of the works then being carried on of the lighthouse proposed to be erected on the Goodwin Sands, and promised to give a drawing showing the construction of the caisson; since then the whole of the works have been destroyed, in consequence of a vessel in one of the severe gales in the middle of October last, during the night running foul of it. Notwithstanding this disaster, we think it will be interesting to our readers to know in what manner the works were carried on, and the construction of the caisson; as the record of failures is frequently of as much benefit as the record of successful works, we have therefore obtained the following reports of its progress, for which and for the cuts we are mainly indebted to the *Nautical Magazine*.

"On the 28th July, at half-past 10 o'clock, P.M., the Monkey steam-tug succeeded in getting Mr. Bush's caisson afloat. She went off from the beach in fine style, maintaining a vertical position during her transit, although she made a good deal of water. The pumps were kept going nearly the whole of the way out. About 5 o'clock, P.M., being at the appointed place, the tug cast off the towing rope, and the caisson soon settled down, though a little out of the perpendicular. She at present declines from north to south about 2 ft. in 24, yet it is believed that, in the operation of sinking the foundation, Mr. Bush will be able to rectify this. One of the large boats from the dockyard accompanied the caisson to the sand, having on board plates for commencing the necessary work immediately.

"On the 16th August, Mr. Bush reported that the caisson was sunk below the sands 16 ft. at low watermark, and that the whole portion was then 42 ft. high, being 9 ft. above high water, and that, in the course of the following week he hoped to add 10 ft. more, with every prospect of speedily finding a foundation suitable for the base of such an undertaking.

"The annexed wood-cut represents the appearance of the caisson on the morning of the 21st of August, showing the mode by which the consecutive iron cylinders were placed over each other to form the building for the lighthouse; and showing also the settlement which had gradually taken place, as well as its inclined position, owing to the sand beneath it giving way over the foundation which is supposed to be of chalk. This inclination Mr. Bush appeared to have overcome by the report, dated the 12th September.

Fig. 1.

"Sept. 2.—Mr. Bush reported that he had in conjunction with Lieutenant Batt, R.N., minutely surveyed the caisson, and found, that after the late stiff breezes it had adjusted itself to a more upright position; that there were 18 ft. of water around it at low water, but at 20 ft. distance there were only 5 ft. A basin had therefore been formed by the strong tides, which proved most satisfactorily that he was but a short distance from the chalk; this was also confirmed by the caisson not having sunk for the three previous weeks more than 5 inches.

"Sept. 12.—Mr. Bush again reported that he, accompanied by Lieutenant Batt, R.N., in Her Majesty's cutter Sealark, made a minute survey of the caisson after the gale, (of the 6th instant,) and found that it had not the slightest effect upon it, and that it remained quite perpendicular after having been subjected for many hours to the violence of the storm."

A small stage was washed off, which was not of any importance whatever; and the spar and derrick. The part shown by the dotted line was also broken away.

Fig. 2.—Section of Caisson.

By a reference to our description in the *Journal* for October last, the annexed engraving, Fig. 2, will explain the construction of the iron caisson.

NOTES ON EARTH WORK, EXCAVATION, CUTTING, AND FORMING EMBANKMENT UPON RAILWAYS.

ARTICLE III.—EXTENT, FORM, AND PROPORTIONS.

"Modern practice has reduced it to a price per cubic yard."
Professor Vignoles' Lecture, Dec. 1841.

In my two previous communications (see pages 84 and 186 of the present volume,) I have endeavoured to show what is the price of earth work, taking ordinary soil as the standard, and then stated the price of excavation to be 4½d., and of forming embankment under one mile in length to be 12d. and 3d. extra per additional mile; and taking the average length to which earth has been led, I find earthwork to have cost on the following lines, Midland Counties, 13d., Derby and Birmingham, 12½d., Great Western, 12d., and North Union, 10½d. I have also stated, at page 186, the extent to which it is prudent to employ horse power to be 2½ miles, and even when there is a steam horse, as the locomotive was once named, it is not prudent to carry earth more than 4 miles. I now propose to consider whether it be not more economical to run excavation to spoil where it is got, and purchase earth on the spot where it is wanted, and for embankment to get it from a side cutting out of the line of railway. At page 84 of the present volume I have given a table of the cost of back cutting or earth excavation from or in the line of intended railway. I now, for the sake of comparison, give a similar table of the cost of side cutting.

The side cutting was of similar material to the cutting in line of railway formerly described, and was made from an angular severance; the length of the side of the triangle next the line was about 20 chains long, and the embankment formed was about 12 ft. in length, about 12,000 cubic yards were moved without the aid of rails, by barrows only; the total quantity being about 40,000 yards; out of 26,000 yards that were moved, 18,000 were got within 20 yards of the edge of the railway, 6000 within 35 yards, and 2000 beyond 35 yards. The contractor was paid per cubic yard 6d. within 20 yards, 7½d. within 35 yards, and 8½d. for all beyond that distance. As a security for the performance of the contract, one penny per cubic yard was retained out of his payments, until half the quantity was performed, and he was paid 1d. per cubic yard extra for ballast, which was raised from the

bottom with horse runs. By a comparison with the price paid for the former cutting, it will be seen that no great difference exists as to price, neither as to the expedition of the one process over the other. The preceding and following tables were obtained by a close attention and personal superintendence of several months, and at an expense that few contractors would go to. The number of wagons were counted by the sub-contractor at the face of the work, and by a person at the tip on the part of the employer; in one case the sub-contractor had bribed the counter to make a false return of the number, but as he was not content with a small defalcation, it was found out on the second day. Had it been otherwise, the defalcation would have been difficult of detection, as from natural causes, weather, lost time, difference of the earth's tenacity, the number of yards excavated by each man employed, varying as much as cent per cent.

TABLE OF COST OF EXCAVATION FROM SIDE CUTTING.

1837	No. of days' work.	No. of Wagons of 2½ c. yds.	No. of Wagons of 1½ c. yds.	Cubic yds. per man.
March 11	258	40	1452	8½
18	248	84	1150	8 nearly.
25	358	243	1302	7½
April 1	376	338	1324	6 full.
8	312	213	1251	8 nearly.

TABLE OF THE NUMBER OF MEN TO NUMBER OF WAGONS.

No. of Men.	No. of Days.	No. of Wagons of 2½ c. yds. each.	No. of Wagons of 1½ c. yd. each.
50	1	..	185
50	1	..	275
50	1	..	294
54	1	17	216
54	1	25	133
49	1	14	190
60	1	61	201
22	1	9	138
51	1	45	239
52	2	31	406
60	2	119	447
60	1	61	201
60	1	58	246
22	1	9	138
54	1	25	133
54	1	41	203
54	1	31	181
54	1	36	192
36	4	48	754
50	3	5	744
52	2	31	406

By comparing the above table with the former tables, it will be found that side cutting is a small fraction cheaper, but the extra quantity of materials and consequent expense will make the two processes equal or nearly so.

Now that the excavation is to be executed at both ends, it will cost only 9d., and having previously stated four miles as the distance or extent to which it is prudent earth should be transported, the cost of which is estimated at 1s. 9d. by the scale of leadage I have the difference of 1s. to play upon. Let us suppose that the land for side cutting is entirely destroyed, and that it was purchased at the rate of 70s. per acre, and that the excavation could be got down 6 feet over the whole surface without having to contend with water, which would be as much as could be done, the locality of embankment being valley, often abounding in water; under the above circumstances, the earth would cost excavating 4d. per cubic yard, at the side cutting end, and if the value of the land at the spoil end be calculated at half the purchase price, which is only injured, not destroyed, it will cost 2d. per cubic yard more, making, with the cost of excavating, 6d., which will leave 6d.; this will pay for carrying the earth 2 miles further than first estimated, hence six miles will be the horizontal extent to which earth work can be removed with prudence, or the point where back cuttings, with a leadage of 4 miles, and side cutting with a leadage of 6 miles, will cost equal or 1s. 9d. per cubic yard.

Having disposed of the horizontal extent to which earthwork may be removed, I will now consider the transverse extent, and the comparison of the cost at one end of open cutting with tunnel, and at the other end embankment with viaduct; I will first then proceed to show where the cost of

1 The Table in the last March No., p. 85, col. 2, line 26, should be, "the fourth the cubic yards moved per man," instead of "the fourth the price per cubic yard."

a tunnel and cutting coincide, taking the cost of a lineal yard of tunnel at £40, and the cost of earthwork at 1s. per cubic yard; when the transverse sectional areas amount to 800 superficial yards, the value of the two will coincide and give us the transverse extent of cuttings.

Then as to embankments, taking the number of cubic yards in the transverse area at 1s. per cubic yard, and the price of brickwork for viaducts at 1s. per cubic foot, or 27s. per cubic yard, then the two prices will coincide when the cubical contents of brickwork in any given length of viaduct is 27 times the cubical contents of an embankment of the same length.

The most extensive excavation known to me is the Cowran, on the Newcastle and Carlisle Railway, which is 40 chains long, and averages 43 ft. deep, its greatest depth is 112 feet; the material is sand without water, and the slopes are 1½ to 1. The highest mound or embankment is also in the North, on the Hartlepool Railway, which is 80 feet high. The amount of earthwork per mile on the Midland Counties Railway, London and Birmingham, and North Union, were respectively 100,000, 107,000, 125,000, cubic yards.

There are other embankments of considerable extent in the North of England, and on the Bishop Auckland and Weasdale Railway. The Denburn Brook, Etherly Dean, Gaunless, and Wear embankments are of the respective heights of 48, 71, 78, and 50 feet. On the Hartlepool Railway, the Hesleton Dene, Edder Acres, and Pespool embankments, are respectively of the height of 80, 70, and 60 feet. On the Clarence Railway there is the Whitton embankment 75 feet high, and the Stillington embankment 60 feet high. The cutting will be as a matter of course of an analogous extent; there are on the Clarence Railway, the Russel, Whitton and Badda Hill cuttings, of the depth of 30, 42, and 67 feet, the latter through new red sandstone, and their cubic contents are respectively 400,000, 220,000, and 200,000 cubic yards, being nearly equal in extent to any of the works on the far famed Liverpool and Manchester Railway.

The form of embankment will depend on the material of which they are composed, and the angle at which the slopes will stand. The ratio has been stated to be

For cutting under 20 feet deep	..	1½	to	1
Ditto exceeding	..	2	to	1
For embankments exceeding 50	..	2½	to	1
Ditto under do.	..	2	to	1

Formation levels are regulated by the gauge of the railway, and distance between the tracks of the road, and proper allowance for side drains. On the Great Western, where the gauge is 7 feet, and the distance between the two roads is 6 feet, the width of cutting at the formation level is 29½ feet and 31 feet, and embankments 34½ feet, and between parapets of bridge 30 feet. On other lines where the old gauge of 4 feet 8½ inches is used, and the distance between the two roads 4 ft. 8½ in. also, a uniform breadth of 27 ft. is used. A considerable difference of opinion exists on this subject, viz., the proper gauge of railway; and it is supposed to be a gauge between the two above-named, the Eastern Counties having adopted 5 ft., the Scotch Railway 5½ ft., the Irish Commissioners 6 ft., and the Belfast and Armagh 6 ft. 2 in.

To return to the Great Western, the width at level of rails in cutting is 40 ft., level of ballast 25, 26½, and 28 ft. On the Midland Counties Railway the formation and cutting was 27 ft., as also the top of ballast, and of embankment 40 ft., being 5½ ft. wider than the Great Western, although the old gauge was adopted. This is the only line where earth in mounds 3½ ft. high was made along the embankment to act as a parapet; this was the reason of the extra width: these mounds were abandoned on account of their expense and their subsiding unequally.

The following rule of progress of earthwork on the Midland Counties Railway I extract from the local papers, being returned by Mr. Thomas Woodhouse, who I believe is the only engineer who has given such a complete one to the public.

	No. of Men.	No. of cubic yards per month.	No. of Horses.	No. of Locomotives.	Stationary engines.
1839.					
23rd March to 20th April	5071	374,085	511	3	1
20th April to 18th May	5138	297,960	513	3	2
4th June to 30th June	4038	13,933	2385	"	"
27th Aug. to 22nd Sept.	4373	203,037	438	1	"
22nd Sept. to 27th Oct.	4597	284,160	498	1	1
27th Oct. to 24th Nov.	4485	210,722	505	1	1
24th Nov. to 29th Dec.	4035	195,174	457	2	1

On the sections of railways, the formation level is shown by a black line, the level of top of ballast by a blue line, and the level of top of rail by a red line.

The following are the mishaps which have been most prominently before the public. On the Great Western, the Sunning cutting in Berkshire, 57 ft. deep, with slopes 2 to 1. On the Croyden Railway, at New Cross, about 5000 cu. yards slipped, and stopped the traffic, the stratum being plastic clay intermixed with strata of sand and gravel. On the North Union, the Ribble embankment 45 ft. high, principally sand, with a 20 ft. culvert, fell in; a similar occurrence, with an 8 ft. culvert and 40 ft. embankment, happened at Paddington, on the Great Western Railway. The Hanwell embankment, on the same line, about 70 ft. high, sunk about 13 ft. in one night, in consequence of being seated on a soft clay, the turf, hedges and trees were displaced at a distance of 100 yards on the south side of the line; it was remedied by weighting and increasing the ratio of the slopes, and by driving an adit to drain off the water. A bridge of 3 arches had to be taken down on the Pontop and South Shields Railway, being forced in by pressure of embankment; on the deck branch of the Brandling Junction Railway, a similar event took place. I have enumerated the above with no invidious feeling, but merely to show that a considerable allowance is due to contractors for their risk in upholding works after completion, which is now generally compulsory for the first year after their completion. In conclusion, I refer you to the quotation at the head of this paper, from Professor Vignoles, and I trust I have answered the query as to the price per cubic yard in actual pence; the Professor in a subsequent section states, "the price of earthwork abstractedly, is the amount of work that an able bodied man can perform in a day." I wish the Professor had given the amount of work done by an able bodied man, and not dealt so exclusively in generalities.

I had prepared a table of the principal cuttings and embankments on the various public works, giving the local name of each, with the length, depth, quantity in cubic yards, value of the strata, time occupied in execution, the ratio of the slopes, and as far as could be ascertained, the cost per cubic yard, as also the datum line of the several railways, and the highest summit yet overcome above the level of the sea; but I was afraid of unnecessarily occupying the pages of the *Journal* with superfluous matter, and merely now state that the Northern lines are as heavy as the Southern in extent of individual knolls, as the following brief comparison will show. Northern lines;—Hartlepool, Crunden cut, 800,000 cubic yards; Clarence, Russell's cut, 400,000 cubic yards. Southern lines;—Liverpool and Manchester, Olive Mount excavation 480,000; Kenyon 800,000; Edge Hill 220,000; Ram Hill 220,000. The now almost forgotten Cromford and High Peak Railway is the most extensive in rock excavations, principally of the hardest mountain limestone, and 168,000 cubic yards have been taken from one hill; this line has more variety of strata than most others, going through sandstone, clay, clunch, shale, freestone, lime, and grit. An elaborate account is published in the Companion to the British Almanac, 1830, by Thomas Woodhouse, Esq., C. E. Extensive as the above works are, they are surpassed by Telford's canal works at Birmingham, the Bloomfield cut being 80 chains long and 90 ft. deep, containing 1,000,000 cubic yards; the Smethwick 160 chains long, 71 ft. deep, and containing 4,697,000 cubic yards, and being executed in 2½ years, the slopes being 1½ to 1. I will perhaps return to this subject again, and give superintendence, account, and measurement.

St. Ann's, Newcastle-on-Tyne.

O. T.

RE-OPENING OF THE TEMPLE CHURCH.

It is natural to anticipate with eagerness, and to contemplate with something of exultation, the re-opening of a long closed religious edifice; and when, as in the case of the Temple church, the charms of antiquity combine with the claims of sanctity to render laudable a liberal, yet reverent, restoration, every one must enter into the feelings, blending in some degree the pleasurable and the proud, with which the modern Templars flocked to their ancient church, so worthily honoured by its present guardians—so hallowed by associations of the past. Invested by age with no common historical interest, its site half consecrated by memories of the enthusiastic, though mistaken piety of its warlike founders—its existing form presenting a noble specimen of Gothic architecture in all its chastened beauty, its solemn dignity, and grand simplicity—it has been restored with a liberality which, lavish as it was, was not only directed by the purest taste, but controlled by the most discerning judgment; and, above all, by that deep reverence for the venerable antiquity, and that due regard for the nature and sacred character of the building, which allowed not even generosity to be misled, nor permitted an ardent desire for the accumulating of all the honours which re-

spect could dictate or wealth supply, to alter the edifice one jot more than was requisite to lend renewed durability to its antique beauty, nor to heap upon a Christian church a too meretricious adornment. On the one hand, then, we were gratified at finding the design of the building a little changed; and that, even in details, the alterations were not only in the way of renovation, but principally, in the strictest sense, of restoration. The church is a noble exemplification of the unquestionable, but often forgotten truth, that the true sublime depends not upon size; and, that simplicity is, after all, a main element, alike in the beautiful and the grand. Nothing can be more simple, yet nothing more truly imposing—striking with a sense of blended grace and grandeur, than the interior architecture; the two rows of dark-coloured marble, rising in slender yet stately beauty like trunks of lofty trees, while the equally simple yet surpassingly lovely tracery of the arches which from their summits realize an enduring embodiment of the artless interlacing and the overhanging foliage of a noble grove. The round church at the entrance is spacious, and, opening into the body of the building, affords an unobstructed view right through to the chancel, over which and nearly along the whole breadth of that end are seen splendid painted windows, the colours of which, bright in pristine beauty, are certainly as brilliant and as beautiful as any we remember to have seen—blending in softened hues the glowing purple or the milder violet, “the cloudy crimson or the misty blue;” through which streams “the dim religious light,” admirably harmonizing with the restored colours of the roof, which, with the more subdued tints of the side windows, give an air of warmth and repose to the edifice quite in keeping with the general tone of its Gothic architecture. The continuity of view, so essential to the sense of grandeur, is not broken by any obstruction, the organ being in a side recess; the pulpit and reading desk masked in the line of pillars on each side (though in the best positions for audibility); and the interior as little as possible broken up for purposes of seats—there being no pews, properly so called; the students’ benches in the centre and stalls at the sides—so that the general impression, at first sight, is that of chaste and simple beauty, and every subsequent view serves to deepen the feeling of the softened harmony that pervades the whole, while over all

“the spirit of the gray old time
“Still breathes around the fane an awe sublime,”—

though no longer, from “the shining mail and banners free” of its early occupants “flashes the light of ancient chivalry.” Everything, indeed, throughout the interior manifests a just appreciation and a constant feeling of the sacred character of a church: this is equally apparent in the studious abstinence from all inappropriate adornments, and in a careful attention to all the important accompaniments of service, as is exemplified in the liberal supply of prayer-books and bibles. The benchers have been evidently guided throughout by a desire to adopt the just medium between a meretricious magnificence, out of keeping with the character of a church, and a cold correctness, equally at variance with the majestic style of the architecture. Their aim has been to make all adornments harmonize with the spirit of the ancient design, an allusion to which was not inappropriately made by the Master of the Temple when referring, at the close of his sermon, to the restoration of the building. He deprecated (while applauding the homage paid by wealth to religion) a departure, in the decoration of such ancient churches, from the beautiful simplicity of their general design, which (he observed) in this case eminently exemplified how much better our ancestors understood the character of sacred architecture than their descendants; there should, he said, be nothing in the way of ornament calculated to attract attention too particularly to itself; while, on the other hand, there ought to be a general tone in harmony with the grand beauty of a Gothic edifice. Assuredly, the architecture of such buildings was the design of those who “dreamt not of a perishable home”—who felt that “feelings which from Heaven are shed” naturally ally themselves to sympathies of kindred, though perchance of subordinate nature;—and that while man is influenced by the spirit breathed into his “inner senses” through the medium of external objects, it might be well to enlist these influences on the side of the sacred and the eternal; and if in some sort a superstitious spirit, impelled by a natural and not improper ardour for the heaping on religion all imaginable honour, induced them to transgress the legitimate limits, and lose the distinction, severing the subordinate from the superior, theirs was an error into which, perhaps, there is less danger of our falling than that contrary one, of imagining (in the words of an eloquent living preacher) “that in religion, more than in other cases, men can be entirely independent of associations;”—of supposing (as said Robest Hall) “that there need be

no very great difference between a temple dedicated to the Most High and a common building”—the mistake of thinking that it can be wrong to invest the “outward and visible” appliances of religious worship with as much of attraction as is consistent with a due sense of the distinction so justly pointed out by the Master of the Temple, who remarked that there was nothing around him which could have the effect of diverting attention from the object and design of edifices so sacred; and though, indeed, it might be that to strangers accustomed to churches of humbler architecture, there might be something at first view exceedingly splendid in the aspect of the interior, the effect of a very little familiarity would be a feeling of entire appropriateness, consistency, and harmony—

“The arch and architrave divinely grand;
“The fairy fretwork of the cunning hand;
“The harmony of stone, the coloured light
“That gleams through rainbow windows dimly bright—
“How can we gaze, nor turn from earth to heaven,
“As though some finer sense were newly given?”

You felt that there was nothing in all you saw about you to detract from, rather to enhance, the feelings of devotion; that it was something, at all events, if not all, to have thus ministered amid

“The sanctities combined
“By art to unsensualize the mind,”

incitements tending “to raise the heart and lead the will by a bright ladder to the world above;” and while listening to the “pealing organ” and the “solemn chant” of the cathedral service (conducted, as it was, in a manner so subdued and so chastened as to be enough to silence for ever the cold and shallow stigmatizers of such chanting, as necessarily savouring in any degree of aught save the harmonious and the hallowed,) its music seemed “lingering and wandering” (in Wordsworth’s lovely language)—

“Like thoughts, whose very sweetness yielded proof
“That they were born for immortality.”

You felt that these were influences calculated “not to divert, but to inspire;” that they served “without offence, to aught of highest, holiest influence” (still borrowing from the great poet of our age), but to “recall the wandering soul to sympathize with what man hopes from Heaven;” and to produce impressions perfectly consistent with the beautiful liturgy (admirably read,) and with the impressive and able discourse of the Master, which we should be desirous of describing from memory, did not respect, alike for the preacher and his theme, forbid us.

For ourselves, in the feelings which pervaded our mind at the close of this first, in (we trust) the long uninterrupted succession of future services in this noble church, where mingled gratitude to the benchers of these societies whose funds they have with so much munificence expended in this highest of all objects; and gratitude, more remote in its application, to the founders of those ancient institutions, which thus act as conservators of so much that is valuable and venerable, and whose powers are so worthily applied to the employment of wealth in a manner calculated, beyond the more immediate results of their liberality in the renovation of a building which is their noblest heritage, to afford an example worthy of every possible imitation in the restoration of similar memorials of ages assuredly nobler in their religious foundations, though not so orthodox in their religious faith as is our own; in preserving (that is) all that is valuable in legacies of the past, for purposes most sacred and most important to the present. And if the mind could not altogether exclude the recollections of those misguided warriors, whose name and whose memory yet linger on the spot which centuries ago their stern enthusiasm hallowed, it was not, perhaps, an unfounded idea that as from their church nothing has been removed that was at all necessary to the simple harmony of its majestic design, so amid the more peaceful fraternities that have succeeded them their virtues have not been discarded along with the alloy of their superstition; but that, with a more enlightened liberality, there survives among the modern Templars all the high and honourable feeling (without its accompanying delusions) which for the most part characterized the Templars of old.—*Times*.

Royal Steam Navy.—A handsome and powerful steam-vessel is ordered to be built, and named the “Trident,” and it is probable she will be constructed for the sole use of Her Majesty. The vessel is expected to be ready for launching at an early period next season. The Trident will be equal, if not of larger dimensions, to the *Derivation*, and will be fitted with the compact and superior engines invented by Messrs. Maudslays and Field. The port at which she will be built is not yet known, but Pembroke has been named as the most likely place, the slips in the other dockyards suitable for building her being already appropriated for other vessels.

NOTES ON STEAM NAVIGATION.

Paddle floats are usually either of fir 3 in. thick or elm 2½ in. thick. Each float should consist of only one piece, either from being cut off a plank as wide as the float, or from the pieces being bolted together edgewise if consisting of more than one. These bolts should go right through the float edgewise with a head on the one end and clinched on a ring at the other. There should be 3 in each float, and in distributing them care should be taken that they do not come in the way of the bolts which attach the floats to the arms.

Paddle bolts and plates constitute an item of considerable expenditure, especially if the ship's carpenter is negligent in screwing up the bolts firmly. New floats are particularly liable to become loose from the compression of the timber, and the bolts should therefore be tightened on every convenient opportunity. It is not uncommon to nick the thread of each paddle bolt with a chisel to prevent the nut from unscrewing, but this will seldom be necessary if the bolts be properly screwed up. When a float is broken, which will sometimes occur in a heavy sea, some of the paddle bolts will generally be lost, but none ought to be lost from any other cause. The carpenter in getting new bolts should always fetch back the old ones, if only to show that there has been no considerable loss from negligence. On one of the outward voyages of the British Queen she lost every float on the weather wheel, and was placed in considerable peril in consequence. This we are inclined to attribute to the circumstance of the bolts not having been tightened after they had been shifted. The vessel on the occasion to which we refer had been in dock, and all the floats had been removed to enable her to go in. When she came out the floats were replaced, and we doubt not the bolts were screwed as tight as possible. This was in London: the vessel then started for Southampton, where the bolts should all have been tightened before she put to sea; but this we believe was not done, and the exposed wheel lost all its floats in consequence. Some of the floats indeed were probably broken by the violence of the waves, but the greater number we suspect were lost from the slackness of the bolts.

Against the rapid erosion of the paddle bolts by the sea water we know of no defence except frequent painting. The wheels should be well painted with red lead about four times a year. Red lead is, we think, a better protection to the iron than coal tar, and is much more manageable in its application. It will penetrate into all the joints and minute interstices which coal tar will not do, and will also adhere to the iron more firmly. Coal tar will sometimes peel off, especially if the wheel has been at all wet at the time of its application; and the iron will not unfrequently rust beneath the coal tar.

As paddle bolts are an article of large consumption, it is of course desirable to produce them with as little labour as possible. The practice of the London engineers is to wind a bar of square iron round an upright mandril fixed in the ground in the same manner as the links of cables are made, and then to cut every round of the spiral in two places; so that every round of the spiral will make two bolts. The mandril must of course be of the figure formed by placing two bolts with the point of the one touching the hook of the other. The nuts of the paddle bolts should not be hexagonal but square, and the carpenter should be provided with two or three good stout spanners that will fit on the nuts easily. These spanners should be single ended; the handles should be straight, and furnished with a hole at the end, through which a rope yarn should be rove. Whenever the spanner is used, the rope yarn should be tied to the rim of the wheel, so as to prevent the spanner from being lost should it happen to slip or fall from the man's hands into the water. Sufficient length of rope yarn should of course be left to permit the spanner to be wrought without impediment. The nuts of the paddle bolts may be quite well stamped in a die; a good stout punching press will answer very well for the compressing power.

Horse power.—There is a blessed uncertainty among engineers as to what area of piston and length of stroke constitutes a H. P.; in fact every engineer appears to have a measure of his own, whereby about as much confusion is introduced into engine making as would arise among the haberdashers if every shopkeeper had a yard measure of greater or less length than his neighbour. A horse power is as much a conventional unit as a pound avoirdupois, and we think it a disgrace to the Institution of Civil Engineers that it has not accurately defined what a horse power is. Mr. Watt, it is true, determined a horse power to be 33,000lb. raised one foot high in a minute; but, however useful such a standard may be for the power exerted by an engine with the power exerted by horses or any other species of prime mover, it is wholly useless for commercial purposes. In short it may inform you of the power actually exerted by any engine, but not of the number of horses power which a given diameter of cylinder and

length of stroke are equivalent to. If a man purchases an engine he is charged at the rate of so many pounds sterling per horse power, and how is he to ascertain whether he has that number of horses power or not? He has no means of finding out, because it has not been defined what a nominal horse power is, and every engineer makes it a different quantity. Thus the West India mail packets are all said to be of the same power, but he will be very far out who shall conclude from them that all the cylinders are of the same diameter. Messrs. Maudslays 400 H.P. is about 72 in. diameter of cylinder.

Messrs. Miller & Co.'s H.P. is about 74 in., which is just about as reasonable as the man's foot should be twelve inches and another only ten. A given sized cylinder, if devoted to the propulsion of a vessel through the water, is rated differently from what it would be if used for any purpose on land. And in Messrs. Maudslays marine engines, while a cylinder of 47½ in. diameter and 5 ft. stroke is rated at 80 H.P., if on the side lever plan, a 48 inch cylinder and 5ft. 6in. stroke is only rated at 75 H.P., if on their double cylinder construction. Such capricious variations appear to us extremely reprehensible, and are calculated, we think, to give a false impression of the force of a new kind of engine or defraud purchasers of a part of their measure in the old kind. The power of an engine ought manifestly to be some function of the cubical capacity of the cylinder, and that function should not be determined by abstract or scientific views, but by the intent to equalize the cost of production for the same power whatever be the stroke and diameter. In other words an engine of the same power should cost the same money whether its stroke be longer or shorter than that of other engines, any increment in the stroke being so compensated for by a decrement in the diameter, so as to keep the expense of production unaltered. This standard, it is true, would no longer be a measure of the power exerted, but of the expense incurred, and therefore "horse power" might be an inappropriate name for it. But the term horse power is not even now expressive of the real power an engine exerts, at least in common language. The actual power is sometimes determined for scientific purposes by means of the indicator, but it is by the nominal power that engines are bought and sold and always spoken of, unless when the contrary is expressly stated. The term horse power is therefore as applicable to the proposed new measure as to the existing one, yet we think a better term might be invented.

The following is Boulton and Watt's rule for determining the nominal horses power.

Let D = the diameter of the cylinder in inches.

V = half the velocity of the piston in feet per minute.

Then $\frac{(D^2 - 4D)V}{2650}$ = the number of nominal horses power.

But how is V to be determined before perhaps the engine has been made? Boulton and Watt fixed upon an empirical velocity for each different length of stroke. The several velocities are as follow.

stroke.						velocity.
ft. in.						ft.
2 0	..	..	..	..	..	160
2 6	..	..	..	..	..	170
3 0	..	..	..	..	..	180
3 6	..	..	..	..	..	190
4 0	..	..	..	..	..	200
4 6	..	..	..	..	..	210
5 0	..	..	..	..	..	220

And so on with 10 feet of additional velocity for every 6 inches of additional stroke. Yet this rule does not give results answerable to the dimensions observed by Boulton and Watt in their marine engines. Thus the original engines of the Thames and Shannon constructed by Boulton and Watt, were rated at 80 H.P., the cylinders being 47½ in. in diameter, and the length of the stroke 4ft. 6in. $(47.5)^2 - 4(47.5) = 2066.25 \times 105 = 217930 \div 2650 = 83$ H.P. nearly, instead of 80. Land engines of 43½ in. diameter of cylinder and 8 ft. stroke, making 16 double strokes in a minute, were rated by Boulton and Watt at 80 H.P. The average effective pressure on the piston is rated at barely 7lb. per square inch, and the power may be thus computed, $(43.5)^2 \times .7854 = 1486.2 \times$ by 7 and 266, and $\div$ by 33,000 = about 80 H.P. In marine engines a greater area of piston is allowed to represent a horse power than in land engines, because the motion of the piston is supposed to be slower, but the effective force is calculated a little higher, or at 7.3 per square inch.

To heighten all this perplexity, M. Pambour proclaims to all nations that the boiler is the true measure of an engine's power, and with the forwardness proper to a little knowledge, maintains this to be a discovery of his own. All engineers and most amateurs have long known that the power produced by an engine is proportional simply to the steam expended, provided there be no accidental cir-

cumstances to influence the result, and that the piston be not made to travel at an extreme velocity. M. Pambour's discovery, therefore, contributes nothing to our knowledge of the subject, unless it be his intention to allege that the power of an engine is to be determined by gauging the boiler instead of the cylinder. If this be his aim we willingly surrender to him the full credit of the ingenious suggestion.

We trust the Institution of Civil Engineers will give their early attention to this subject, and define what function of the length and diameter of a cylinder a horse power should be, so that a uniformity of measurement may be established among engineers, and purchasers may know what they are buying. Should this not be done by the Institution we shall attempt the task ourselves—giving the proportion of our principal engineers, the rules for finding those proportions, and a new unit of our own.

Surcharged steam.—The question has been frequently raised whether steam to which a high temperature has been imparted without increasing its elasticity is more economical than common steam. The specific heat of steam has been found by experiment to be 847, that of water being 1, and if this result is to be relied on, there appears to be a saving worth attending to in the use of surcharged steam. Yet it appears questionable to us whether the specific heat of steam is not the same as water, the apparent diversity arising from some error in the experiment, which indeed in researches of such delicacy it is almost impossible to exclude. There are many analogies in favour of the conclusion that the specific heats of bodies are inversely as the atomic weights, and if that doctrine be true, the specific heats of steam and water must be the same. Yet great economy is said to have been realized by the use of surcharged steam, and upon the whole it seems worth while to inquire what amount of benefit may be expected from surcharged steam at a given temperature supposing the specific heat of steam be such as has been determined by experiment.

If θ denote the density of the steam, then $45 \left(\frac{1}{\theta} - \theta \right)$ will denote the diminution of temperature when the steam is rarified to unity, or the number of degrees requisite to be added to maintain the temperature unchanged. The latent heat of steam being 1000° , the heat necessary to raise water from 60° into steam is $1000 + 152 = 1152^\circ$, and if the steam after leaving the water at the temperature of 212° be heated to 600° , and at the same time be prevented from expanding, $600^\circ - 212^\circ = 388^\circ =$ equal the heat requisite to be added if the specific heat of steam were the same as that of water. But the specific heat of steam is 847.

$$\therefore 1 : 847 :: 388 : 328$$

Supposing now the steam be allowed to expand,

$$\begin{array}{l} 448 + 212 = 660 \\ 448 + 600 = 1048 \end{array} \left. \vphantom{\begin{array}{l} 448 + 212 = 660 \\ 448 + 600 = 1048 \end{array}} \right\} 660 : 1048 :: 100 : 158.8 \text{ or say } 159.$$

or the steam when permitted to expand, will occupy 159 volumes at the original atmospheric pressure. The density of the steam when

so expanded will be $\frac{100}{159} = .629$ $\therefore 45 \left(\frac{1}{.629} - .629 \right) =$ the heat

absorbed by the steam during its expansion from 100 to 159 volumes,

$$45 \left(\frac{1}{.629} - .629 \right) = 45 \left(\frac{1}{.629} - \frac{.629^2}{.629} \right) = 45 \left(\frac{1}{.629} - \frac{.401641}{.629} \right)$$

$$= 45 \left(\frac{.598359}{.629} \right) = 26.025015 \text{ degrees. This is the result}$$

for air, the specific heat of which is .2669.

$$\therefore .2669 : .847 :: 26 : 82^\circ.$$

The total quantity of heat therefore requisite to produce 159 volumes of surcharged steam of the atmospheric pressure and temperature, 600° is $1152 + 328 + 82 = 1562^\circ$. To raise an equal quantity in the common way would require 1831.68° , for

$$100 : 1152 :: 159 : 1831.68^\circ \text{ say } 1832.$$

$$\therefore 1832 - 1562 = 270^\circ \text{ and } 270 \div 1862 = \frac{1}{6.7} \text{ of the whole heat;}$$

in other words, by surcharging the steam to the temperature of 600° the saving is a little more than a seventh of the whole fuel consumed.

Deck Plates.—Every steam vessel should have an iron deck plate above the steam chest: the fore and aft bearers of the boiler hatch should also be of wrought iron. Boiler plate on edge with angle irons at top and bottom answers well. Dog bolts may still be used in the beams extending from the fore and after to the ship's side, and the knees can be placed as usual.

Safety valve chest.—The weights should all lie within the chest or

within the boiler. The practice of raising the valves by palms acting on the lower extremities of the valve spindles, and attaching the weights *beneath* the valve with a cutter, which admits those weights to be raised without lifting the valve, is, we think, a good practice. The valve can thus be *eased* without opening it, which is done by relieving the valve of its lower weights, the weights *above* the valve still keeping it down, though with a diminished force. By raising the palms still more, the cutter arrives at the end of the slit in the socket, and then the valve is lifted. The safety valves seat should never be driven tight in and rivetted, but attached by means of a weak flange and a few weak bolts, so that the valve seat would be raised out of its place by the pressure of the steam before the boiler would be burst. The waste steam pipe should always be attached to the safety valve chest by a socket joint. If fixed by a flange it will speedily be cracked at the neck from the rolling of the chimney, when the vessel is in a sea way, the funnel shrouds never being so tight as to prevent *all* motion of the chimney.

Slide valves.—Messrs. Maudslays make all their slide valves up to 50 H.P., of the long D description, above that power, short D. Their long D's are just the same as those in common use, but the attachment to the valve rod is at the top instead of at the bottom as is usual. The covers of the valve casings are made so that they may be moved in as the valve faces wear, the bolt holes being oblong, and the part where the joint is faced in the lathe. The joint is made with a piece of sheet lead *not* wrapped with canvass. The valve rods are steel; the long D's are of iron, the short D's of brass. Messrs. Miller & Co. also make their short D's of brass. The practice is an excellent one.

HYDRAULIC PROPULSION ON RAILWAYS.

Of the many plans to which the fertile ingenuity of the present day has given birth, for the purpose of diminishing the cost and danger of railway locomotion, the most novel in design, and amongst the most recently invented, is the Hydraulic Railway, for which Mr. Shuttleworth, of Manchester, has taken out a patent. The principle of the invention was announced 12 months ago, but the patentee has since made considerable alterations in his original plans for carrying his design into execution. For the purpose of making it more generally known, he has just published a pamphlet setting forth the claims of his invention, describing at great length its proposed mode of operation, and calculating minutely the advantages to be derived from the adoption of this system of propulsion on railways. Independently of the ingenuity of the invention, which claims notice on that account alone, the consideration of the subject gives rise to some interesting questions relative to the motions of fluids, that well deserve attention. We propose, therefore, shortly to describe Mr. Shuttleworth's invention; to state the principal grounds and calculations on which he rests its claims for adoption; and by an examination of the phenomena and laws of hydrodynamics bearing on the subject, to ascertain whether this mode of propulsion can be rendered practically available.

The arrangements proposed by Mr. Shuttleworth for carrying his plan into operation, are in their general features similar to those of the atmospheric railway. A pipe a foot in diameter, with a longitudinal slit on the top, is to be fixed between the rails. Within this pipe a piston is to work, which is to receive the propelling impulse, and communicate it to the carriages by means of a connecting rod passing through the opening at the top of the pipe; which slit is to be kept closed by a continuous valve. So far the two plans exactly agree, and in Mr. Shuttleworth's first proposed mode of working the hydraulic railway, its resemblance to the atmospheric was still further continued. His intention was then to employ an exhausting pump, worked by a stationary engine, the pipes being filled with water. The advantage proposed to be gained by employing water instead of air in the pipes was the greater facility by which a vacuum could be obtained by exhausting an inelastic fluid. At that period Mr. Shuttleworth did not seem to have made sufficient allowance for the friction of the water in the pipes, nor for the weight of water the stationary engine would have had to drag along with great velocity. The resistance presented by these causes of retardation would, however, have required far more power to overcome than the weight and friction of a rope, the disadvantage of which it was a principal object of the invention to obviate. It is true, that Mr. Shuttleworth from the first development of his plan contemplated the occasional application of the direct pressure of a column of water, as an additional means of propulsion; but he seemed to rely principally on the power to be gained by the pressure of the atmosphere on the water forced through the horizontal pipes, to supply the place of the water pumped from that portion of the pipe in advance of the piston.

The plan of working by hydraulic propulsion now proposed, which is detailed at great length in the pamphlet before us, has effected a complete change in the mode first intended. Mr. Shuttleworth now relies entirely for the propulsive power on the pressure of a column of water, acting against the pressure of the atmosphere, without any exhaustion. He proposes to have reservoirs of water, of sufficient height to produce a pressure of six atmospheres, placed at short distances along the line of railway. From these reservoirs vertical pipes, of the same diameter as the horizontal, are to convey the water to the commencement of each section of propulsive piping. The length of each of these sections is to be about 70 or 80 yards, and the termination of each section of propulsive piping Mr. Shuttleworth proposes to connect with double its length of what he terms "skeleton piping," along which the railway carriages are to be propelled by the momentum previously acquired. In the intervals between the running of the trains, it is proposed to employ stationary engines of great power to pump the water back again to the elevated reservoirs.

The foregoing is an outline of the principal features of the hydraulic railway. The advantages which are expected to result from its adoption are, diminished cost in the mode of working, increased safety, by the avoidance of collisions, and greater facility in the construction of railways in hilly countries. Mr. Shuttleworth makes various calculations for the purpose of showing the economy of his system of propulsion compared with that by locomotive engines; but into these details we do not propose now to enter. Our present purpose is to examine the principles on which he founds the hydraulic mode of propulsion; for if these prove to be defective, as we believe them to be, it will be useless to inquire further.

The first great error into which we conceive Mr. Shuttleworth has fallen, is in the calculation of the initial velocity that could be communicated to the carriages by a vertical column of water of the same diameter as the horizontal pipe. He professes to take all his data from the best authorities in hydrodynamics, among whom Mr. Tredgold ranks foremost, and it is only due to Mr. S. to say that he claims no more in favour of his plan than the calculations of the authorities he relies on seem to warrant. His fault, like that of many other ingenious inventors, lies in the attempt to apply general principles to particular circumstances wherein those principles are inapplicable. Founding on Mr. Tredgold's formulæ, Mr. Shuttleworth estimates the velocity of water rushing from the bottom of a column 198 ft. high to be equal to $67\frac{1}{2}$ miles an hour; this, therefore, he assumes to be the initial velocity which might be communicated to the train of carriages on the hydraulic railway. Now, granting that water would rush from a small aperture at the bottom of such a vertical column with a velocity of $67\frac{1}{2}$ miles an hour; we cannot concede that the *whole column* would rush out with that velocity. According to theoretical estimates, water rushes from an orifice with the velocity which a body falling freely would acquire in moving through a space equal to the height of the water above the orifice; but many circumstances may cause the velocity of the issuing fluid to deviate from this general law. If the size of the aperture approximate to that of the tube, the velocity will be diminished; and if the aperture be of the same size as the tube, so that the whole column of water must fall as rapidly as the issuing fluid, the velocity will be diminished one half, without making any allowance for friction. That this must be the case will appear from the circumstances attending the fall of a column of any other body the particles of which cohere. The accelerated motion acquired by all bodies in their descent, would naturally give to the water towards the bottom of the vertical pipe a much greater velocity than to the water at the top; and were the particles of the fluid without cohesion, they would separate into drops in their fall, instead of acting in one connected column. The cohesion of the particles is, however, sufficient to prevent this separation, and the fluid column must, therefore, move with an uniform velocity, in the same manner as a chain or a rope thrown over a pulley must fall throughout its whole length with uniform velocity. The lower portions of the water or chain which, if detached, would move with greatly accelerated velocity, are retarded in their descent by adhering to the more slowly moving portions above, to which they in turn impart some of their superior momentum gained in the descent. The communication of velocity from the lower portions of the falling column to the upper is evidenced in the flow of water down pipes, by the force with which the water in the reservoir is drawn into the pipe; which force increases with the height. It thus appears, that the resulting velocity of a vertical column of water must be the average motion given by gravitation to the whole; or less than half that which Mr. Shuttleworth calculates would be the initial velocity in his system of propulsion. He might, it is true, obviate this difficulty by greatly enlarging the size of the conduit pipe, but this would materially add to the cost of construction.

Another important error appears in Mr. Shuttleworth's calculations in consequence of the velocity of water flowing freely being considered the measure of its propulsive effort. Now, it is very obvious, that any effort required to propel the train of carriages on the railway must diminish the velocity of the acting fluid; and that in proportion to the velocity communicated to the train, the propulsive effect of the fluid pressure must diminish; for it is only when the pressure is resisted that its effect operates. For example: if the carriages were propelled by some other power at a velocity equal to that with which the water rushed along the horizontal pipe, the fluid would evidently exert no impulsive effort on the piston. If the carriages were propelled with half the velocity of the fluid, then only half the impulsive effort would be exerted; and not until the train was stationary, would the full pressure of the fluid be brought to bear on the piston. The whole of Mr. Shuttleworth's calculations of the power to be derived from hydraulic propulsion would, consequently, only apply to pressure against a stationary resistance: so soon as the train was put in motion the power exerted on the piston would diminish and would continue to decrease in proportion to the increase of speed attained.

One of the objections urged against the system of propulsion by locomotive engines is the great waste of power occasioned by the weight of the engine and tender, yet Mr. Shuttleworth seems to have entirely overlooked the fact, that the same objection applies, in a tenfold degree, to his plan of hydraulic propulsion. He has, indeed, no heavy engine to propel, but the weight and friction of the water, which constitutes his moving power, offer a far greater resistance to motion than an engine and tender. The length of each section of propulsion piping is proposed to be only 70 yards, yet towards the end of that short length the weight of water to be propelled would amount to nearly 5 tons. This weight of water would have to be put in motion with great velocity, with the additional objection of being exposed *throughout its whole course* to retardation by friction in the pipe; whereas the friction of a locomotive engine acts only on those points of the rails whereon the wheels rest. The loss of power by retardation in the tube is, indeed, taken into account by Mr. Shuttleworth, but he appears to overlook the fact that this loss is occasioned by communicating motion to his moving power. The amount of power lost by propelling the water through the pipe is much greater than would at first be supposed. Mr. Shuttleworth himself estimates that his calculated initial velocity of $67\frac{1}{2}$ miles an hour would be reduced in a length of pipe of only 70 yards, to $29\frac{1}{2}$ miles an hour; and in another part of his pamphlet it appears that the estimated initial propulsive power of 693 horses (!) would be reduced, after passing through 70 yards of piping of one foot diameter, to 71 H. P. We have thus, by Mr. Shuttleworth's own showing, a power of 622 horses absolutely lost in propelling the moving power; and that too for the short distance of only 70 yards! Surely no system of railway propulsion was ever before proposed, which by the statement of its inventor exhibited such a waste as this; and yet it is proposed as a means of economizing power!

Nor is this all. An enormous waste would arise also from the attempt to regulate the speed communicated by a power varying, by the estimate, from 693 horses to 71, in the space of 70 yards. To obviate the objection which would be urged against the plan, were the rates of speed to be so unequal, Mr. Shuttleworth proposes to fix a self-acting throttle-valve at the commencement of each section of propulsion piping, so as to reduce his estimated initial velocity of $67\frac{1}{2}$ to 27 miles an hour. Thus nearly two-thirds of the power would be absolutely thrown away for the purpose of regulating the speed to agree with that of the terminal velocity of the water. Mr. S. appears to imagine, however, that this check on the flow of the water, would not diminish the pressure, because, according to the laws of hydrostatics, the pressure is as the base of the resistance, and that the area of the piston would therefore sustain the same pressure however small the opening of communication from the vertical column of water. He forgets that this law obtains only in fluids at rest; and that as soon as the piston moved under the impulse of the whole vertical column of water, the impulsive force would be diminished. If the throttle-valve were so regulated as to reduce the velocity to 27 miles an hour, the pressure on the piston would correspond with that velocity, and not with the pressure of the whole vertical column. All the force lost by checking the water at the throttle-valve would consequently be so much power wasted.

It might be supposed from the lavish waste of power which is exhibited throughout the whole plan of the hydraulic railway, that the inventor had at command the falls of Niagara every 200 yards of his proposed line; the waters of which he could send rushing through the pipes without any limitation. Not so, however, for every drop of water thus uselessly squandered is to be forced back again into artificial reservoirs. Of these reservoirs, indeed, though they form an

essential part of his system, he makes but little mention. In the construction of a railway on the hydraulic propulsion plan, they would, we conceive, figure rather prominently among the items of expenditure, and add very materially to the engineering "difficulties" of any line of railway. The erection of immense towers 200 ft. high every 200 yards, would present formidable obstacles to the trial of such a mode of railway propulsion, even did it present theoretically much greater advantages than those claimed for the hydraulic; and unless our views are exceedingly erroneous, the plan could never be practically carried into execution, in consequence of the immense waste of power which every part of it presents. We have, we think, pointed out sufficient instances of this waste to justify our opinion, but on reading over Mr. Shuttleworth's "plain statement" others will be found which we have not thought it necessary to enumerate. Objectionable as Mr. Shuttleworth's first plan of the hydraulic railway appeared, we consider it far preferable to his "improved" mode of employing the water propulsively. The principle of exhaustion, on which it depended, is more simple, and its effects would be more certain, and produced with vastly less expenditure of power.

We regret to be obliged to decide so unfavourably on the claims of an invention which bears evident marks of great ingenuity and labour; but we consider it much more to the interest of an inventor, who has been misled by the application of erroneous data, to endeavour at once to convince him of his error, than to indulge fallacious hopes, which can only end in more bitter disappointment.

THE ARCHITECTURAL SOCIETIES.

SIR—In this age of novelty, locomotion, and substitution of new powers for those approved in days of yore, can we wonder at any of the attempts made by Ecclesiastical Commissioners, of whose "crusade against the employment of architects" T. H. W. so justly complains, or other *Joint-stock* societies, such as one recently established in the North, which professes to follow the Oxford and Cambridge architectural societies, and that they should submit to them any plans which may be made for building new churches, or for *restoring old ones*, as prepared by their builders or their builders' clerks, (for architects will be out of the question,) under their immediate *direction and dictation*; albeit their knowledge is obtained entirely from *Glossaries* and other books, which are *compiled* from works, *sometimes* possibly correct, but more frequently *artificial plates*, made for effect only, and when examined and compared with the work intended to be represented, cause the inquirer to think whether a wrong plate may not have been bound up with the work by mistake; there will be of course much experimentalizing by the new parsonage house commissioners, and the builders in many places will have to conform to the views of their architect, who composes his plans by the fire-side, for why need he trouble himself about local peculiarities, and what *cares he* about the gaping and wondering of the country boobies, at seeing a trim brick and plaster house, built upon a stone quarry, when the material excavated from the cellars, would have built the walls of the house at half the expense, and twice the durability; the rage is now all for a bit of Gothic, or at least Elizabethan, for possibly a work published a few years ago, (the "*Principles of design in architecture*,") has tended to put away the "*Gothic and tasty*" lintels cut up to a peak over a door, when a horizontal one would have been stronger and produced a better effect; formerly the indented battlement or parapet was all the rage, now the pointed gables, as irregular as it is possible to make them—one in the entrance front with windows ranged like a ship's port holes, and much in the same proportion, and the other close to it in the same line with a huge projecting chimney stack, covered with mouldings and shields, for what purpose only known to the designer. Strips of wood cut into holes of all shapes, quatrefoil, trefoil and wavy, according to Rickman, *barge boards*, (certainly as appropriate as the rest of the structure in such a situation,) placed under each of the gables—now the Architectural Societies intend to *copy* and to *restore*; at least *so they say*: but when are they to give their knowledge? The prospectus of the new Yorkshire Society contains the names of two architects only, and neither of them attended the Autumn meeting. *Two meetings* are to be held in the year, and from the information given at the last, it appears, that for *general accommodation*, they are to be in the remote corners of the country; all admitted must be members of the Established High Anglo-Catholic Church! the committee, of young clergymen, and amateurs, who *read*, and *look at pictures*, are to be the *bees*,¹ *if they can be got to work*; all the rest are to be considered as

*drone*s, and only called together in the Spring and Autumn, to see the produce of the hive. As far as could be seen after the last meeting, the secretaries constituted the society—two clergymen and a surgeon, the *latter very young*. From this society is to be *directed* the restoration of the architectural gems of the country, and woe to any architect, who dares venture upon a slight variation, if even better to remove the work of a subsequent period, and restore the earlier and better parts. It is time for the architects to awaken from their *lethargy*, or if awake, *their apathy*, as they alone can be expected to guide the uninitiated in the profession, and make them so far of use, that (as throughout the country there is a feeling in favour of the Ecclesiastical buildings of the middle ages, evidently the works of the clergy and their *free brethren*), they may work together, and discover the source from which the beauties of those temples spring.

I am, Sir, &c.,

A

DR. PAYERNE'S EXPERIMENTS ON THE DIVING BELL.

[WE received from Dr. Payerne, but too late for insertion last month, a letter complaining of our remarks on his diving bell experiments. It is but fair to the Doctor to publish his reclamation, to which we shall add a rejoinder, in justice to ourselves.]

SIR—He who undertakes to treat a subject which he does not understand, is liable to fall into the deepest error. Of this truth the reporter of the experiments made by me on different occasions in the diving bell, furnishes, unfortunately for himself, too glaring an instance in the October number of your Journal. I shall not, in order to prove this, lose myself, after his example, in a maze of suppositions all equally gratuitous, not even excepting the emphatic preamble in which he exclaims against the whole English press, to whom I tender my sincere thanks for its favourable notice of the success of my experiments, a notice which has done me the more honour, as it was altogether unsolicited.

One idea in which the reporter, as he reverts to it in every line, indulges with much complacency, is the supposed pompous announcement by me of the discovery of a new process for generating air by decomposing water, and thereby producing the necessary oxygen to support life. Upon what authentic grounds, I will ask him, does he rest his pretended report? Is there not reason to believe, until he condescends to reveal its source, that he has attempted wittingly to impose upon the judgment of your readers? He indeed never will, but I can proclaim its source; he has collected his notes, not on the spot where the experiments were made, nor in accordance with the principles developed in the esteemed works upon chemistry and physiology of which he is ignorant, but in the shop of a third or fourth rate provincial chemist, a declared enemy of Major-General Pasley, who did not think fit to receive, with implicit faith, the light offered to him by this pretender. It shall be my business to show that Major-General Pasley has unvaryingly adhered to the truth, and that the reporter is egregiously ignorant of the commonest laws of pneumatics.

The diving bell in which my experiments were made at Spithead, is but 5 feet high, 4 feet long, and 2½ feet broad. The seat therein is about 18 inches above the bottom, so that our shoulders did not rise above 3 feet 3 inches. These data known, I am obliged, in order to be understood by the reporter, to enter upon a few elementary explanations upon the compressibility of air under a given pressure. It has been an established fact, since the period of Mariotte and Boyle's experiments, that all gaseous substances become compressed in an inverse ratio with the pressure to which they are subjected. It is a fact no less true, that a column of water about 33 feet high, after removal of the air above, will counterbalance the terrestrial atmosphere. But when the latter and the column of water simultaneously press with their whole weight upon a gaseous substance or upon air, it becomes condensed to one-half of the volume which is filled when subjected to a single pressure of one or other of those agents. This law once well understood, it becomes evident that, at the depth of 33 feet of water, subject to the pressure of the atmosphere, the quantity of air contained in the diving bell at the instant of immersion, will be reduced to one-half of its original volume, and that the water will rise to one-half of the height of the diving bell, namely 2½ feet. If an atmospheric pressure be added to the former twofold pressure, the volume of air, already reduced one-half, will be further reduced by one-third, that is to say, that the water will rise 10 inches higher, or 3 feet 4 inches, a height already more than sufficient to immerse us shoulders deep in the water. If to this height be added that which should have been produced by an additional column of 8 or 10 feet of

¹ The standard for all buildings is to be Parker's Oxford Glossary.

water, it will be seen that Major-General Pasley, instead of exaggerating, has rather restricted facts with that reserve which belongs only to men of real learning, who advance nothing but what they are in a condition to establish beyond dispute.

The reporter lays it down as an axiom, that one gallon of air suffices to support life during one minute. I beg of him to inform us upon what scientific authorities he rests his reasoning. Unless he dares to challenge the conclusions of the French Institute, and especially the recent experiments made by Messrs. Leblanc and Dumas, it has been demonstrated by the whole body of the learned, that a man inhales in one hour about 200 gallons of air, and that he requires 8 times that quantity in a shut up place, for the well-established reason that a portion of air issuing from the bronchia, renders 8 portions of pure air unfit for the support of life. The result from this fact is, that the diving bell of the Polytechnic Institution, containing 80 feet of cubic air only, instead of 140, as the reporter dares to affirm, or 500 gallons instead of 870, a diver, without the help of my process, could not remain therein more than 20 minutes. The pretended experiments which are alleged to have been made subsequently to mine, and which deserve to be styled mysterious far more than those to which this epithet has been so injudiciously ascribed, have been witnessed by no one; and had they really taken place, as is alleged, the actors therein must have been driven out of the diving bell by a degree of suffering past endurance, whereas in my experiments I was not sensible of the slightest inconvenience, and was drawn up without having expressed a wish to that effect, and solely because the term allotted for the experiment had expired. In a word, I can remain in the diving bell an indefinite period of time.

What would you have me answer to the absurd supposition that I profess to enable a man to inhale water at the bottom of the ocean, instead of air?

The dimensions of the diving bell at Spithead are already known. The cylinders, according to an exact evaluation, did not hold more than 70 cubic feet of air, at a pressure of 30 in., and not 220 ft., as the reporter alleges. According to the beautiful experiments of Mons. Leblanc, the whole quantity of air contained in the 2 cylinders and the diving bell would have been scarcely sufficient for 2 men during one quarter of an hour. But the difficulty of living any length of time under water was not the question I wished to elucidate or settle at Spithead, that problem having been resolved at the Polytechnic Institution. The object I had in view has been attained in the most complete manner, namely, that of proving that the diving bell being once filled with air, under a given pressure, it was unnecessary, with the help of my process for living under water, to keep up a constant supply of fresh air, for the reason, that an even pressure would keep the water out of the diving-bell during an indefinite period. These reasons alone prevented us from prolonging our confinement in the depths of the sea. The reporter has not understood them: but I can well spare his commendation, provided as I am with the honourable attestations of those eminently competent gentlemen who witnessed my experiments. Their testimony is, in my opinion, of at least as much value as the opinions of a writer who seeks information in the shop of a man who was not, as I can prove, even present at the experiments in question.

I have said enough, sir, to convince you that your reporter having rested his arguments upon a foundation avowedly unsound, all his conclusions are consequently erroneous, and that I had no need to attempt to conceal a failure, in a case where I had obtained a most complete success.

Dismissing his other assertions which are not worth contradicting, let us conclude that your reporter undertook a task above his reach in attempting to handle a question involving principles of chemistry, natural philosophy and physiology, three sciences of which he does not possess the common elementary notions; and, admitting that he may be less ignorant upon other subjects, I still claim the privilege of recommending to his notice the old adage: *Ne sutor ultra crepidum*.

I remain, Sir,

Your obedient servant,

DR. PAYERNE.

[Of the tone of Dr. Payerne's letter we do not complain. He is evidently smarting under the infliction of our former article, in which was exposed the extravagant puffing his performances had been honoured with in the newspapers; and, under the circumstances, we can readily excuse his discourteous expressions. Of what we do complain are, the mystifications and misstatements by which it is attempted to convey the idea that he has made some wonderful discovery, whilst he carefully avoids mentioning explicitly what it is that he claims to have discovered, and of what the nature of it consists. It appears from the latter part of Dr. Payerne's letter, he enters

the opinion that the article commenting on his experiments was written by some one who "obtained his information in the shop of a man who was not even present at the experiments in question." We are entirely at a loss to conceive to whom he alludes, and in this respect we are as completely mystified as he could wish us to be regarding the properties of his revivifying apparatus. Our comments on the experiments at Spithead were, and professed to be, founded entirely on the report in the *Times*, which bore the character of being semi-official, and of being written by some friend of Dr. Payerne's. Our object was to prove that all Dr. P. was stated to have accomplished by the aid of his apparatus for purifying and generating air, might have been done without any apparatus whatever; and to correct the erroneous notions generally entertained respecting the quantities of air required to sustain life in confined situations. We think we completely succeeded in those objects by the statement of a few simple facts and experiments; but as Dr. Payerne now questions their correctness, we must return to some of the points advanced, with a view to set them at rest more conclusively.

Dr. Payerne adduces the authority of the *savans* of the *Academie des Sciences* against our calculations and facts respecting the quantities of air necessary to support life. We are certainly not so presumptuous as to challenge all the philosophers of the French Institute, but we may be allowed to question the inferences which Dr. Payerne draws from their researches, in favour of his own views; especially when they can be proved to be diametrically opposed to well established facts. He asks on what authority we asserted that one gallon of air is sufficient to support life for one minute; and as he appears to pay great deference to authorities, he may be disposed to admit that the names of Messrs. Allen & Pepys deserve consideration. Those accurate investigators of truth performed several experiments, with a view to ascertain the quantity of air absolutely necessary to support life; and the results are reported in the *Philosophical Transactions* of the Royal Society for 1808. We did not, however, state that one gallon of air per minute is sufficient for continued respiration, but that life might be supported by one gallon per minute for a short period. We expressly stated that the increasing deterioration of the air would render a larger quantity necessary, excepting for a short continuance, and we made ample allowance accordingly. There is no doubt that air containing a large proportion of carbonic acid gas is unfit for continued respiration, but the question between us and Dr. Payerne is, how long can a man continue to respire the same air without serious inconvenience; for on that point rests the value of his experiments as a test of his announced discovery. Even M. Leblanc, whose authority Dr. Payerne quotes, shows clearly that the supply of air deemed *desirable* is far from being *necessary*. In his memoir read to the Academy of Sciences, M. Leblanc states, rather vaguely, that the quantity of air required for healthy respiration by one person is from six to ten cubic metres per hour, yet he mentions at the same time that in the lecture room of the Sorbonne, when the windows are closed, the quantity of air admitted does not amount to one cubic metre each person. But putting aside all inferences drawn from analyses of the air, the claims of Dr. Payerne, which rest on his experiments in the diving bell at the Polytechnic Institution, must be annihilated if it be proved that other persons, without any apparatus, have remained equally long under water in the same bell. It seems that we were in error when stating the capacity of the bell to be 870 gallons. We have since measured it, and find its height to be 5 feet, and the diameter 4 feet; which give an internal capacity of about 62 cubic feet, or only 387 gallons. The space occupied by two persons cannot be estimated at less than 5 cubic feet, equal to about 31 gallons; therefore the bell, when occupied by two persons, would not contain more than 356 gallons of air. This is much less than we originally stated the bell to hold; and if this smaller quantity of air proved sufficient to support the respiration of two persons for an hour and a half, it confirms the more strongly our original position respecting the quantity of air absolutely necessary to support life. Dr. Payerne feels this, therefore he denies that such an experiment could have taken place, and even ventures to affirm that the "pretended experiments" were witnessed by no one. The experiment *was* witnessed by a gentleman who communicated the fact to us, and on subsequent inquiry at the Polytechnic Institution, his statement that the parties descended, and remained in the bell without external communication for an hour and a half, burning a candle, too, during a great portion of the time, was confirmed.

In order to remove all doubt on the subject, the Editor of this Journal was determined to try the experiment himself, accordingly he, accompanied by another gentleman, descended in the diving bell at the West India Docks, the use of which was obligingly afforded for this purpose. That bell is larger than the one at the Polytechnic Institution. Its height is 4 ft. 8 in., length 5 ft. 8 in., and breadth

3 ft. 8 in., its net capacity about 520 gallons; and the space occupied by two individuals would reduce the contents to about 490 gallons of air. To avoid any complication in the experiment by the introduction of more air than the actual contents of the bell, and the necessity of taking down cylinders with compressed air, to prevent the water rising in the bell, it was lowered so that the whole of the bell was immersed 9 inches below the surface of the water, sufficiently to effectually exclude all external air without compressing the air within too much. The experiment commenced at three o'clock, and was continued until half past four. In this time no inconvenience was experienced from the deterioration of the air in the bell, and in their opinion they might have remained at least half an hour longer, but the approaching darkness induced them to give the signal to be drawn up; having fully verified the experiment at the Polytechnic Institution by remaining, without a fresh supply of air, for an hour and a half. If Dr. Payerne has any doubt as to the correctness of the experiment, the Editor will be most happy to accompany the Doctor, and repeat it with him, or any other person he may nominate.

In the first of these experiments the quantity of air in the bell would allow scarcely two gallons, in the latter rather more than two gallons and a half per minute for each individual; yet those limited quantities proved sufficient, without producing any disagreeable sensations whatever.

"Facts are stubborn things," Doctor, and in this instance they will, we expect, prove too obstinate to yield to any mystification, though backed by the authority of the French Institute. No one would descend in a diving bell for fresh air, however supplied, nor select such a residence as a restorative of health; existence in a diving bell,

must, after all, be a matter of endurance, and the facts we have stated show the absurdity of applying vague opinions respecting the quantity of air requisite for healthy respiration, as data for calculations of the quantity of air necessary to support life.

We infer from Dr. Payerne's letter, and from circumstances which have since come to our knowledge, that he now disclaims all pretension to generate oxygen gas, and that he claims only the plan of absorbing the carbonic acid gas resulting from respiration by the use of quick lime and potash. If this be the case, on what foundation does he rest his assertion, that he could "remain in the diving bell an indefinite period of time?" Though Dr. Payerne may, now that his experiments have been submitted to scrutiny, disclaim the power of generating "good air," there is little doubt he in the first instance wished to convey such an impression; else, by what conformity of blundering could all the reporters have agreed in so representing Dr. Payerne's powers. If he did not originally profess to be able to generate oxygen gas, what becomes of the declaration in the semi-official report, that "General Pasley had no doubt of the goodness of the Doctor's air?" and how can he defend the first proposal to descend without any cylinders of compressed air to keep out the water?

We hope we have satisfied Dr. Payerne, or at least the public, that his experiments in the diving bell at the Polytechnic Institution, signally failed to prove that he possesses any peculiar and valuable means of purifying or of generating air; and that his calculations of the quantities required for the support of life are extravagantly erroneous. We will not deny that he has done some good by the announcement of his discoveries; it has attracted attention to the subject, and thereby elicited useful and curious facts.]

SUGAR MAKING APPARATUS.

SIR—The importance of any improvement in the process of "Sugar making," in the colonies, with respect either to economy in the manufacture, or the quality of the product, I trust is a sufficient apology for calling the attention of your readers to a description of an apparatus employed by Mr. Alfred Stillman, an engineer of this city, who has for a number of years been engaged almost exclusively in the introducing and perfecting of steam machinery in the West Indian islands.

This gentleman, having occasion to put in operation a "Steam mill," in St. Croix, conceived the project of converting to the purpose of generating steam for the engine, that vast proportion of the heat from the "megass fire" which is wasted beyond the "coppers." In order to effect this, he placed the steam boilers directly behind the "trains," in such a manner as most effectively to apply the waste heat from under the "coppers." In this he so far succeeded as to require no other fuel for generating steam, than sufficient to "put the mill about" in the commencement of each day's work.

His attention was next turned to the employment of the "exhaust steam" for clarifying the "liquor." To do this, he employed tanks of sheet iron, with double bottoms and traversed by a tier of copper pipes, into which was introduced the escape steam from the engine. The process of clarifying was in this way effectually carried on; and by closing the escape pipe with a loaded valve so as to maintain a slight pressure within, the effect was so much increased, that by means of two or more sets of these tanks, the one discharging into the next, a part or the whole of the process of concentration might be thus performed, and thereby dispense with a part or the whole of the train of coppers, rendering the megass fire more effective under the steam boilers.

Now, it is a point pretty well established in practice, that in the

evaporation of saccharine juices, the less the temperature of the heating surface, the less of oxidation takes place in the saccharine matter, and the more perfect the crystallization; consequently yielding a greater proportion of sugar and of better quality.

Admitting this, it will be perceived that if, instead of the intense heat of the megass fire and the limited heating surface, we employ the temperature of steam with an unlimited extent of heating surface, a decided advantage is gained in these important particulars—the quantity and quality of the product.

The simple sketch accompanying this, will scarcely need further explanation; being merely a section of a reduced train of coppers, A, A, A, with its flue, B, passing from the furnace, C, under and through the two steam boilers. D, D, also two clarifiers, E, F, represented, showing their construction and the manner of admitting the steam.

The whole arrangement and operation is extremely simple, and very readily encompassed by such talent as is to be found on every "sugar estate," which has been satisfactorily demonstrated during the last two years in St. Croix, and also during the past season on the estate of Don Gaspar Hernandez, Cuba, West Indies.

New York, July 1842.

F. W. S.

[Although portions (if not the whole) of the apparatus above described are not new, we have thought proper to give our Transatlantic correspondent's communication an insertion, as it shows what economy there is exercised in the distribution of heat in the process of sugar making. We may at some future opportunity, publish the process of sugar making in vacuo.—EDITOR.]

THE PROFESSORS OF ARCHITECTURE.

1. *Introductory Lecture at King's College.* By WILLIAM HOSKING, F. S. A.; Architect and Civil Engineer, Professor of the Principles and Practice of Architecture, and of Engineering Constructions. London: Weale, 1842.

2. *Preliminary Discourse at University College.* By THOMAS LEVERTON DONALDSON, Vice Pres. R. Inst. B. A. &c.; Professor of Architecture. London: Taylor & Walton, 1842.

It would be unfair, at the present moment, to compare the Professors at the two rival colleges, particularly as one is but on the threshold of his career; we shall therefore consider separately, as far as we can, the discourses by which each opens the present session, giving precedence by seniority to that of Mr. Hosking. The groundwork of this is in the usual introductory lecture style, but the author has managed to introduce his favourite theories. Here he repeats his definition of a civil engineer, that he is only an hydraulic architect, and defines the duties of an architect as those of a civil engineer. Of the propriety of such doctrines we have before intimated our dissent, and also of Mr. Hosking's implied definition, that an architect is not an artist. The architect and the civil engineer have one study in common, that of construction, but they are no more identical on that ground than any two substances are identical, each of which contains an element in common. The design of a civil engineer, and consequently his career, is as distinct from that of an architect as light from dark. St. Peter's and the Birmingham Railway have masonry in common, and they have arches, yet few but Professor Hosking would propose to interchange Bramante and Stephenson. Again, we cannot but note the contemptuous terms in which Mr. Hosking speaks of the artist and of the arts.

"The qualifications of an architect—place him as far beyond the mere artist as the artist is beyond the artisan."

"Architecture and architects suffer together from their association in the public mind with the imitative arts and with mere artists."

"Artists being not unfrequently linked in the same category with players, fiddlers, and dancers."

Judges are linked in the same category with pettifoggers, physicians with quacks, and clergymen with itinerant fanatics, yet we never heard the respectability of law, medicine, or divinity impugned, or that of their professors, and we can conceive no disgrace to a man from being put in the same class with Michael Angelo, Raphael, and Rubens. Mr. Hosking, however, seems determined to treat both architecture and engineering as mere building. Another of Mr. Hosking's peculiarities is about the gentility of architects, and that at present it is scarcely a profession for a gentleman. How this may be we do not know, but we fear that at present neither lawyers, physicians, nor architects, are employed for the length of their pedigrees, the number of their quarterings, or the purity of their descent, but on account of their ability, and that their gentility is in virtue of the liberal nature of their professions. We think it much better that architects should stick to the arts instead of the Herald's College, for the present generation of architects surely cannot be accused of the sin of too much artistical feeling, which is just the quality most deficient. Public opinion and competition are especial bugbears to the Professor, and he recommends his pupils to set both at defiance. We are only fearful that if they do, they will find themselves equally wanting of reputation and employment. The present is not the period either to hold public opinion as naught, or to run counter to it; there are too many educated critics and amateurs, there is too much intelligence in the press, for the old mystery-men to hold their ground, architects must be prepared to account for the faith within them, to defend their errors as well as their merits, and to do as every other art and profession must do, look to the public voice for direction and reward. It is too late to stem the current. As to his depreciating opinion of Vitruvius, Mr. Hosking defends it, and repeats his well known assertion, that "a student would acquire as correct a knowledge of history and of geography from the 'Seven Champions of Christendom' and 'Gulliver's Travels,' as of architecture from Vitruvius." We are not surprised at hearing this, for we know a similar diversity of opinion prevails among lawyers as to the adoption or rejection of "Coke upon Littleton" as the foundation of legal studies. In both cases, however, we consider that the class book is to be esteemed as indispensable, not on account of its positive instruction (which in both cases is of little value), but as the instrument by which the minds of the profession have been moulded, and so, essential to the new student. Mr. Hosking's remarks on competition we must pass over, as also his plan, for they are so foreign to the present state of public feeling, as to be entirely futile. As to the assertion that no competition should

take place between architects, because none exists among lawyers and medical men, it is quite unsupported, for a lawyer or a medical man may have a thousand cases or more in the course of a year, but few architects have half a score buildings to erect in the same period.

Mr. Donaldson begins by recognizing the importance which architecture, within the last twenty years, has assumed in this country, and the deep interest which all classes have taken in its progress, as evinced by the attention paid to it by the public press. He then takes an extensive view of the artistical triumphs of architecture, and concludes by sketching out the main features of his two courses, the artistical and the constructive. The composition is brilliant, and the range of investigation wide, perhaps in some cases too wide, but giving good earnest of the extent of the author's acquirements. We note an opinion as to the merits of Vitruvius, opposite from that we have alluded to in the case of Mr. Hosking.

The following extract of that portion of the Lecture in which the Professor takes a rapid glance of the various styles of architecture, will exhibit to our readers, particularly students, those high attainments, which so well qualify Mr. Donaldson for the responsible office he has undertaken.

Follow me up the Nile which winds its sinuous course through 1000 miles of country, from 10° within the tropic of Cancer to the Mediterranean, presenting a line of abundance and verdure through an expanse of desert. The attention is first attracted by the Pyramids within whose dark recesses may still lie hidden all the secrets, that have hitherto eluded research, to make us acquainted with the arts, the manufactures and the science of the dynasty of the Pharaohs. Memphis and Thebes, Phyle and Abussambul offer their monolithic tombs, their immense excavations, their gorgeous temples, and superb palaces, enveloped in hieroglyphic inscriptions, which still elude our research or ill repay the indefatigable zeal, the unwearied patience and the vast stores of erudition brought to the task of decyphering them; for instead of being pictures of thought they contain the bare records of names.

The contemplation of these masses makes the mind of the traveller revert to the period of Egypt's ancient greatness, when she was the cradle of science to the whole world, and by her progress in the arts and letters influenced the rising genius of Greece. The intelligent observer gives order to the confused piles which lie around him, and fills up the void space from the writings of Dionysius the Halicarnasian and of Strabo. We shall attempt to describe one of the Egyptian fane.

An Egyptian temple appears to have been one of the most imposing assemblage of buildings, that can be well conceived. Avenues lined with hundreds of sphinxes on each side, led the worshipper to the sacred precinct for the distance of thousands of feet; and thus the mind, even when remote from the vicinity of the Temple, received an impression calculated to excite veneration. This avenue was terminated by a stupendous mass of pyramidal form, above 200 ft. wide and about 80 ft. high, whose enormous proportion was naught diminished by the vastness of the plan in which it stands, nor by contrast with the mountains that overhung it. In the centre of this propyleum is a door, flanked in advance by an obelisk on each side, about 90 ft. high, and beside which are figures of colossal dimensions, 45 ft. high, sitting as guardians of the sacred portal. The effect of the whole is gigantic and calculated to impress the coming worshipper with the fullest notions of his insignificance in the scale of material nature. The triumphal gateway being passed, a magnificent court meets the eyes of the beholder, having on each side a colonnade; and this court led to a densely columned hall or vestibule, under the shades of which the crowds of Egypt's sons and daughters reposed to recover from the exhaustion and fatigue caused by their journey under a burning sun to the fane of their creature god. And here the mind also dwelt awhile on the first impressions produced by the contemplation of the overpowering majesty of the gorgeous mass. For the huge popylea, which enclosed either end of the court, and the hall with its forest of clustered columns, which the eye could not number, and the playful variety and copiousness of channelled hieroglyphics which left not a space uncovered, and the brilliancy of the pigment which gave an endless variety to the shafts and capitals of the columns, to the beams, the walls and ceilings, bewildered the attention, and left not a moment of repose to the wondering stranger. A lofty central avenue of columns, above 60 ft. high, forming as it were a triumphal way, leads under a third portal, of dimensions by no means inferior to the others just mentioned, and marked with what care and with what sanctity the priests guarded every approach to the inner parts of the temple. But this gateway passed and a scene the most sublime burst upon the view. An ample peristyle, much larger than the one already passed, presented itself to the eye, probably planted with trees, crowded with metaphoric statues; on either hand a double avenue of columns less for convenience than dignity of effect. In the centre uprose the portico of the mass of building, which formed the Temple itself—the columns in dimension more lofty, in decoration more rich, in proportion more graceful than those of the courts. The dynasties, that had ruled over the country up to the period of the erection of this temple, have their histories graven on the walls and on the columns—the same pyramidal form gives an appearance of endless durability to the mass, which is surmounted by an immense hollowed cavetto having the centre occupied by the sculptured form of the agatho demon, or winged globe and

serpents, with outstretched wings extending over the centre intercolumniation of the façade, and seemingly a being of another world. Admitted beneath this porch, the minds of the worshippers are prepared for the gloomy inner penetralia, where every object was mysterious and emblematic. Numerous doorways closed by curtains succeeded each other, and led from vestibule to vestibule, which hindered the eye from penetrating with sacrilegious gaze into the inmost sanctuary, all access to it being forbidden to the multitude. To these vestibules the light of day was denied, and the mind was subdued by the gloom of the spot: for the attention was absorbed by the contemplation of the sacred mysteries of the place, and by the effects produced on the attention by the huge incongruous figures of granite—monstrous reflections of the gloomy minds of the religious inhabitants of the sacred precinct, who sought to deify matter and the animal instincts. How sad a contrast, that they, who by their mental powers could command such mechanical forces and make such progress in art, should be so debased as to worship the human form distorted by the addition of the head of a bird, of a cat, of a ram, or some such brute object.

We thus see the impressions which Egyptian architecture is calculated to produce, realizing the definition of beauty given by Aristotle, who says that it consists in magnitude and order.—*Τὸ γὰρ καλὸν ἐν μεγέθει καὶ τάξει ἐστὶ*. Poet. p. 2, § 4. One of the temples of Thebes exceeded 800 ft. in length by nearly 300 in breadth exclusive of the avenues which led to it. This vastness of extent in the plan;—gigantic grandeur in the ponderous masses;—colossal proportions in the details;—a rapid succession of similar objects;—the brilliancy of the gold, purple, scarlet, azure, green, and every splendid colour that shone upon the surfaces of the stone;—liable as all this may be to the charge of monotony, yet a series of lively impressions must have been extorted by the grandeur, the pomp, and profusion, which these imposing edifices offer to the bewildered attention. *

Who would brave the sandy wastes of Syria, unless impelled by a glowing love for that sacred volume which records the history of the favoured race to whom were confided the oracles of divine truth, were it not to visit the Decapolis still profuse with architectural remains, almost unexplored, certainly unillustrated. Would the traveller quit the fertile and sublime valley of Baalbec, whither comparative ease and comfort have hitherto accompanied him. Would he plunge into the dangerous track of ancient commerce, beset with hordes of Arab robbers, deprived of every convenience and means of subsistence, but that which he carries with him, were not his privations, his anxieties and his perils to be rewarded by the sight of that which was once Tadmor of the desert, the Palmyra of Zenobia and Longinus. These vast piles of ruins seem the works of those days when "Giants were on the earth" rather than the production of a race like ourselves. Temples enclosed in courts seven or eight hundred feet square, surrounded by circumambient porticos of colossal dimensions—now inhabited by a score or two of wretched families in their mud cottages—avenues of columns, miles in length—a profusion of triumphal arches, lofty towers and tombs, and marble beams in single blocks of 70 feet in length attest the mechanical skill, if not the pure taste of its ancient merchants—for it was a race of merchants who dwelt in this emporium of the commercial traffic from the East, at that time forming the halting place for the caravans, which poured forth the riches, the refinements and the productions of India to gratify the craving appetite for variety and luxury of the pampered nations of Europe.

But let us accompany the traveller in his circuit of these shores and examine with him the coast of Caramania, and we shall find it abounding in a profusion of architectural embellishments. But as soon as he reaches Gnidius, sacred to the queen of love, monuments of the refined taste of the most refined periods again offer themselves, and the ruins of temples, propylea, theatres and in fact every species of edifice offer themselves to notice in Halicarnassus, Miletus, Priene, and Magnesia and the numberless cities which peopled each side of the Meander, the Nile of Asia Minor. Still further north, Teos and Smyrna, Pergamus and Sardis show how truly architecture flourished under the fostering generous splendour of the great Alexander and his successors.

But the traveller, whose mind is imbued with all those associations connected with the study of the literature of Greece, visits Athens as the zealot does the shrine of his saint. When Europe was roused from barbarism her first thought was directed to Athens—"What is become of Athens?" was the universal cry, "and when it was known that her ruins still existed, the learned and ingenious flocked thither as if they had discovered the lost ashes of a parent." (Chateaubriand: Voyages.) When the traveller treads the soil, which had been for so many centuries polluted by the presence of the Moslem, all his feelings arise with double force. He thinks that he now breathes the same pure air, fixes his glance upon the same enchanting scenes, contemplates the same noble monuments, as once did Pericles, Socrates, Demosthenes, Xenophon, Thucydides, Sophocles, and Plato. Possessed however as are his feelings with such thoughts, his attention is more than divided by these majestic ruins, which throw around the spot an air of sanctity. Here Phidias has still his chef-d'œuvre, here the genius of Ictinus still reigns pre-eminent, and the space encircled by the walls of the Athenian Acropolis may be termed the *temple* of architecture, containing temples, altars, statues, groups, trophies, chapels—the spoils of their enemies and the plunder of their allies and friends.

See how much Athens gains upon the affections of every people, of every age, by her architectural ruins. Not a traveller visits Greece whose chief purpose is not centred in the acropolis of Minerva. How dif-

ferent from this the renown derived from arms alone. "While the name of Athens is in every mouth," exclaims Chateaubriand, "Sparta is totally forgotten. Sparta in arms the rival of Athens—the cradle of warriors—the school of hardihood and all the sterner virtues of humanity. But she disdained the accessories of our art, and not our art only, but of every other, for she never offered the smallest incense in the temple of genius, nor on the altar of the arts. In fact, to use the words of one of Sparta's warmest panegyrists, the Lacedemonians drove away from her walls literature, science and the arts, and now not a single monument arrests the steps of the traveller. Civilization is now as far distant from the Eurotas as in former times, and he hurries from the unfriendly spot having cast a rapid glance upon a plain, where nothing records the existence of former times, and a mound at best reminds one, that here has been a city. Even the haughty spirit of the Romans bowed before the mighty influence of the superiority of Athens in art, science, and literature. When Greece was conquered by Rome, Sparta became a mere province, but Athens although depressed, a slave and helpless, without her Pericles, her Phidias, her Ictinus, her Demosthenes, her Sophocles, still asserted her mental superiority, and held in slavery the proud spirits of Rome her conqueror.

"Græcia capta ferum victorem cepit, et artes Intulit agresti Latio."—Horace Epist. lib. 2, ep. 1.

What trial can equal this of the fine arts. O! could the Spartans of old have thus looked into futurity, and they would have emulated that bright love of art to which ancient and modern Athens now owes so much of her perennial glory—for as the refined and accurate Barthélémy has justly and eloquently observed, "the history of the monuments of this people is the history of their exploits, their gratitude and their religion."

But perhaps the attention is wearied by dwelling so long on this portion of the subject, and yet it is impossible to omit all reference to Rome as she is. It is there that a willing homage is yielded to the architecture of ancient periods. The soil which time has accumulated upon her ancient pavements is now being cleared away. Each excavation brings to light some precious fragment, some interesting object connecting antiquity and modern times. Her fora, her temples and circuses; her triumphal arches and lofty sculptured columns; her aqueducts and baths; her palaces and amphitheatres are now minutely investigated by the antiquary, the scholar, and the artist. Hundreds flock annually, less to witness her pomp of religious worship than to imbibe, at the very fountain head, a true love for architecture and a refined taste to appreciate all the excellencies with which the eternal city abounds.

Nor shall Pompeii be altogether unnoticed—hid for centuries from the view of man—her site questioned and her very existence almost doubted as the fable of historians, the ashes are now removed from the tomb in which she had lain for above 15 centuries, and the traveller fancies as his footsteps are echoed through the tenantless fabrics, that the next moment he will see her ancient citizens emerge from the courts of her dwellings, from the shops of her insulae, or from the baths, which still preserve traces of almost recent occupation. It seems as though it were but yesterday that her thousands flocked to the fora, temples, and theatres; and the spot brings us in almost immediate contact with the inhabitants of the olden times. *

Such then are the emotions inspired by the ruins of the ancient monuments of architecture, and such the claims she has upon the gratitude of ancient and modern times, as forming one of the main links, that unites us with those, who have gone before us. Languages become obsolete, but the language of architecture endures for ever. The pages of history may be lost or destroyed, but who can for a moment admit the thought that time can obliterate, although he may deface her monuments. The pyramids and temples of Egypt are imperishable. The habits, the customs, the religion, the wants, the luxuries of man change with each century and with each clime, but for all and every new necessity and fresh desire architecture amply provides.

But in thus rendering the homage due to ancient art it were unjust to pass without notice those sublime edifices due to the genius of our fathers. It is now unnecessary to enter upon the question, whether the first ideas of Gothic architecture were the result of a casual combination of lines or a felicitous adaptation of form derived immediately from nature. But graceful proportion, solemnity of effect, variety of plan, playfulness of outline and the profoundest elements of knowledge of construction, place these edifices on a par with any of ancient times. Less pure in conception and detail, they excel in extent of plan and disposition, and yield not in the mysterious effect produced on the feelings of the worshipper. The sculptured presence of the frowning Jove or the chryselephantine statue of Minerva were necessary to awe the Heathen into devotion. But the presence of the godhead appears, not materially but spiritually, to pervade the whole atmosphere of one of our Gothic cathedrals.

This style, which has aptly been termed Christian architecture, has produced edifices of all descriptions, not only ecclesiastical but civil, evincing great variety and originality; so numerous that we cannot but feel surprised at the public spirit, the devotion and liberality, which could contribute the means requisite for such vast buildings, and at the skill that could, with a hardihood verging on infatuation, so daringly sport with danger, and yet inspire confidence in the wildest flights of Gothic fancy.

GRADIENTS ON RAILWAYS.

THE readers of your valuable Journal will, I have no doubt, be aware that, but a short time since, the opinion of many, if not most, of the eminent engineers of the present day, was, that gradients only of the very first order ought to be employed in the construction of railways intended for passenger traffic, whatever might be the consequent cost. Under this impression we have now completed in this kingdom some of the most magnificent and easy lines of railway in the world, for instance the Great Western, and many others, on all of which, though, it must be owned, that thousands upon thousands of pounds have been expended in order to attain such perfection in gradients. This supposed absolute necessity for easy gradients seems now, however, to be fast losing ground with many of our first engineers, and the result of past experience seems now to say, that "one may pay too dear for one's whistle." So great have been the improvements in the locomotive engine within the last few years, that in the construction of railways at the present time, instead of aiming at absolute perfection in levels, our ablest engineers are now looking more at the original outlay, and the purchasing of good levels only at what they are *really* worth.

For improvements in railways and locomotive engines, people now, however, generally look to the south, instead of the north of England, and in many cases rightly so too, because the improvements in the north have been transferred to the railways in the south, and these improvements have, in some instances, been improved on again; yet methinks the *hot-bed* of railways may still be inspected with profit by an inquiring mind, neither ought one to be disrespectful towards the birth-place of railways, or to pass by unnoticed that part of the kingdom where the locomotive engine, rude as it was at first, came from its maker's hands a hideous monster, alike the terror and wonder of every spectator,—I mean the counties of Northumberland and Durham. And to show that gradients which, by many, are condemned as impracticable for the use of the locomotive engine for passenger traffic, may still be employed where the nature of the surrounding country forbids an alteration for the better, I will state a few particulars as to the work performed by that beautiful machine the locomotive engine, on one of the northern lines, viz. on the Hartlepool Railway.

In the year 1832, an act was obtained for the making of the Hartlepool Railway, and at that time the science of railway engineering had hardly advanced so far as to demand such absolute perfection of levels; consequently, the Hartlepool Railway can by no means be classed amongst the number of those possessing gradients and curves of the first order. The railway was certainly not made to suit the peculiarities of the locomotive engine, consequently the locomotive engine has been obliged to be made to suit it, and upon it may be daily seen a single locomotive engine, with its train of carriages, running up a gradient of 1 in 34 for a mile and a half, at the rate of from 25 to 30 miles an hour, and notwithstanding all the inferiority of gradients, the passenger trains on this railway equal in speed and punctuality any of the more refined and southern lines.

The length of the main line over which the passenger trains run is 12½ miles, and in this short distance it rises nearly 450 feet. For a mile and a half there is a gradient of 1 in 34, and the prevailing gradients for the remainder vary from 1 in 164 to 1 in 274. The gross load, including engine and tender, varies from 35 to 40 tons, and the number of passengers in each train from 60 to 100, and occasionally 120. The engines, "Albert" and "Victoria," with this load mount with ease this tremendous gradient, and I think it may be fairly said that for *hard work* their Majesties set an example worthy of imitation by their subjects both far and near. A few remarks also as to the other traffic on this railway may, perhaps, be worth a passing notice. The number of trains (exclusive of passenger trains) that pass along this railway in a day varies from 60 to 120, and at times amounts to 140. The time occupied for the transit of this enormous traffic is about 13 hours per day, or an average of a train in every 5½ minutes to 11 minutes during the day. The gross weight that passes over the rails varies from 7 to 12 tons per minute for 13 hours per day, and occasionally, during the present year, it has exceeded an average of 13½ tons per minute for 13 successive hours! What but an *iron road* could withstand such a traffic as this. So that, instead of the passenger trains on the Hartlepool Railway meeting with peculiar facilities, both as to gradients and non-obstruction in consequence of heavy traffic thereon (as the charge for fares would seem to warrant), the reverse is the case. Seldom during the running of the passenger trains are there less than six other trains on the railway at the same time, in the first four miles. So that what with the engines having to wind their way through this labyrinth of engines and trains, and at the same time to encounter

gradients that would frighten some of the first engineers of the day, the passenger trains are performing daily, unheard of and unnoticed, on the Hartlepool Railway, what may be safely said is not being performed on any other railway in the kingdom, and probably in the world, and that at a charge, too, to the passenger, very considerably lower than on other railways possessing gradients so immensely superior. The table underneath shows the comparative cost per mile of travelling on the following railways, and without further comment thereon for the present, I will conclude these remarks:—

		1st class.	2nd class.	3rd class.
London and Brighton	..	3·44	2·26	1·42
London and Birmingham	..	3·20	2·13	
Great Western	..	3·05	2·13	1·27
Hartlepool Railway	..	1·47	1·22	0·81

S. T. N.

SCHOOLS OF DESIGN.

SIR—In the Somerset House Drawing Book, No. 1, it is laid down:—

1st. That ornamental art, as an imitative art, ranks midway between fine art and mechanical art, and partakes of the nature of both.

2nd. That the fine arts, in dealing with poetry, history, and moral expression, occupy a ground in which the ornamentist has no right to enter!

And yet thirdly, that on *beauty*, the artist and ornamentist occupy the same ground!

Again, the author says the power of imitating objects artistically, is not adequate to the ends the ornamentist has in view, and yet at page 3, the author says, "It is not merely with lines the ornamentist has to do, he has often to represent the colour and effect of metallic substances, the glitter of gems, in short to make a picture of the article manufactured, which shall show its general character and appearance, rather than the exact details of its form and ornament, and there is no other way of acquiring the power of doing this, than by the habit of copying, as an artist, the objects themselves or similar ones."

Again he says, the ornamentist arrives at practice through science—the artist to science through practice.

And yet he says in the same page, "a saving of time would be effected, if the chief labour at commencement were bestowed (by the ornamentist) on drawing by the hand!"

In reply to these inconsistencies, I beg leave to state that—

1st. The ornamentist and the artist, both express their thoughts and inventions by the mechanical operation of imitating natural objects by form, colour, and light and shadow. Imitation of natural objects is, therefore, the basis of both ornamental art and high art, and the easiest plan of practising the eye to see, the brain to conclude, and the hand to obey, is the best plan at the beginning, both for ornamentist and artist.

A student may puzzle his memory so long by scientific distinctions, if he begin by science, as to find when he has acquired science his hand perfectly helpless; and, therefore, both in the case of the ornamentist and artist, a certain degree of *purblind practice* of hand, eye, and brain, is absolutely necessary for the highest genius in each department, as well as the humblest, so that when their minds comprehend any principle of science, or any object of nature, their hands may at once be able to illustrate them by design.

No great artist of the Greek and Italian schools was considered a great artist without science, and no great ornamentist was considered a great ornamentist unless he was a great artist too. Raffaello was a great ornamentist; Giovanni d'Udine, and Cellini, were artists as well as ornamentists, and the foundation of both characters is first, a *power of imitating* what you see.

There is no doubt the imitation of senseless angles and cones, and octagons and pentagons, may generate a dead sort of mechanical imitation, but the mind of the mechanic and artist sleeps, because there is nothing whatever to interest their sensibilities in the progress; give them beautiful eyes, their sympathies are excited, and the circle and ellipsis being portions in the shape of eyes, they acquire the same power of imitation, and exercise their powers of thinking too—follow eyes by the nose, they learn the perpendicular—let them then practice the mouth, they are obliged to make it horizontal, or at right angles with the perpendicular of the nose; the shape of the head is an ellipse, the forehead and chin, portions of the circle.

A human head is thus got through—combined with a human look, and a human expression; the students *feel* as they proceed; what practice for geometrical designs is left out in the figure? Then come action, repose, intention, and thought, by circles, ellipses, angles, and perpendiculars, but combined as a whole to convey a meaning; when the artist and mechanic are got thus far, show them if you please, where is the geometry of the head and figure, practice them in angles and circles, that they may know

their meaning; make them both men of science, if you like, and let the mechanic begin to branch off—but begin with making both skilful in hand, eye, and brain, by imitating the same object, for according to our author at Somerset House, “a saving of time would then be engendered, if the chief labour at first were drawing by the hand.”

If the power of imitation be the first power to be acquired, as I have proved, both from what I have said and what our opponent says, why separate the education of artist and mechanic? But what will you say, or he say, when he acknowledges that in the most important of all qualities of design, viz., *beauty*, the artist and mechanic stand on the same ground, and yet he would separate their education? And though he admits, page 1, they stand on the same ground, yet, he again says, they proceed to exhibit beauty by a method totally the reverse to each other!

“Beauty,” says he, “with the ornamentist, is a quality separable from natural objects.” I reply it cannot be. Beauty, with the ornamentist, from whatever form taken and applied, excites the emotion in the work of the ornamentist, not because it is separated from the object to which it naturally belongs, but because to whatever object applied, it has the power of again exciting the emotion, as it did when a component part of its natural object at first.

If a sculptor, says he, makes a lily, he models a lily. “Not so the ornamentist—the lily appears in his hands with a *new individuality*.” Of course, but it is still a lily—the ornamentist makes it a cup, a vase, but I reply it is still a lily turned into a vase and cup—and if it be not like a lily, what would a sensible master say to a mechanic who showed him a cup made of a lily. “A lily! it is not a bit like a lily. Pray did you model a lily, or draw a lily?” “No Sir, I did not, because we ornamentists treat lilies with a *new individuality*.” Very true, my pupil, but to be able to give a new individuality to a lily, you must first be able to form a lily in clay, or by drawing; to model or draw a lily, you must get a lily and study it; after studying it, you must imitate it by modelling or drawing. Imitation is the foundation of all arts or design, whether for the artist or ornamentist, and though the ornamentist turns a lily into a new office, if he cannot imitate a lily or a human figure, somebody else must be employed to do them for him, and this must prove to you, my pupil, the necessity of the ornamentist and the artist beginning alike. Because what applies to the lily will apply to the figure, and the arguments are as good in one case as the other, and both prove the same truth.

The author proceeds to say “that the ornamentist and the artist are imitators of nature, but in different senses—in the one, the resemblance is fictitious, in the other a reality.” I reply the resemblance in both is fictitious, and in both a reality, though the application is different.

The basis of all this sophistry is simply this: the London leading artists had been so accustomed to be by their rank, their payment, their honour, and their privilege, a *distinct class*, that they were shocked by any attempt to revive the old connexion between artist and artizan. It was a sculptor, though rising from humble but respectable parents, who first intimated the insult of giving the artizan an education, which would rank him more as an artist than, for 300 years, he had hitherto been, in England, and, of course, without any imputation on the honourable motives of any one now; we all know there is a degree of sensibility as to duty, in defending the views of our superiors, if to them we owe our station and our existence in life—it is right it should be so, perhaps I do not know if one is not inclined to respect gratitude, if even it lead a man into the most egregious folly.

It is a question, if the education of the mechanic be not of more importance than the great artist's. See how he worms himself into all the ramifications of domestic decoration, and consider, if he had, like the German and the Frenchman, the power of conveying his thoughts by drawing the figure, how prettily, at a little cost, the drawing-room of the middle classes, or their parlour, or their bed-room, might be made vehicles of history, and poetry, and design. The more the power of design is diffused, the greater, and not the less will be the employment of the great painters. The wealthy and the noble will always have the best of everything, and they who love the handsomest women, drink the best wines, ride the best horses, and claim the highest stations, will not be very apt to desert the best artists, when they want their efforts. I am decidedly of Burke's opinion, “whatever turns attention to art, even the purchase of old pictures,” said he “reflects again on modern painters.”

Never, I assure you, was British art in greater danger than now. This London school, by separating the artist and the mechanic, and promulgating the doctrine, that sound art and decorative art are distinct, will, in all probability, do more mischief than a century will remedy—because the facility of admission is great, young artists go to it, and all the horrors of gaudiness, glare, hardness, and false taste, will spread like wildfire amongst the rising generation.

What reason can be given, that a flower should look in decoration like botanical preparations, pasted flat on lime? Distinctness is necessary, of course, but why cannot imitations of nature be distinct, without being inconsistent with the eternal principles of the great masters, established by the greatest geniuses the world ever saw.

Titian, Velasquez, Rubens, Rembrandt, and Reynolds, made their imitations of nature on the basis of the philosophy of human sensations.

Equalities of effect distract! variety is necessary, but if carried too far, pains. It is the same with every quality of imitation in the great works of the great masters, no individual requisite of imitating life is ever obtruded, whereas, by the separation of the education of the artist and the mechanic, the imitations of the mechanic at present are all obtrusion and totally inconsistent with sound art. If a race of this offensive description issue out, as designers for glass paintings for rooms, for halls, what will the art be like in a few years? The combination of sound art can be seen to perfection in a glass window at Liverpool, where a fine picture has been copied, with all the principles of imitation; it is a fine work of art in manufacture, and that is what should be the object in all Schools of Design.

Not long since, returning from Windsor, I went into the coffee-room of the Royal Hotel, at Slough, and found the paper on the walls full of pretty designs, from Faust (I believe). “Is this English,” said I. “English,” said the waiter, with an air quite insufferable, “French, sir, of course!” Here is another case in point. Had the same principles of educating the mechanic been acted on at Lyons as in London, would this French artizan have been able so to please us in the middle class by such a display, and is not every visitor excited and improved by such a simple way of recalling the scenes of some beautiful poems?

I apologize for this long intrusion; my engagements preclude the possibility of continuing this important question, but I promise it shall not rest whilst I live, for I know its vast national importance and that we have only to add mastery to design to our indisputable quality of material, to take the lead in the world.

In conclusion, I deny in toto, that the mechanic has no right to mingle history, poetry, and moral expression, in his manufacturing design; what right has any man, or any body of men, to fix a limit to the exercise of human ingenuity? The Almighty sometimes gifts a Byron, and sometimes a Burns, and reflects on the principles of our own noble aristocracy. Who, more tenacious of their rights, but who more useful as a check on the Crown and the people? and who is refused admission into their class, even from the *humblest* amongst us, if genius, guided by conduct and decorum, prove any individual worthy to be a great lawyer, soldier, sailor, or statesman? If it were not for this wise decision, what would have become of the Aristocracy long ago?—and with such an aristocracy in Government, are we to establish one in art, where no genius, no decorum, and no conduct, will procure elevation and reward for the humble mechanic? Ridiculous—the bare thought and promulgation will make us the laughter of Europe, if this preface has not done so long since.

The artists must become more workmen, and the workmen more artists, before the great revolution, beginning will begin aright; but it will not be by putting forth theories which will separate them more and more than ever, but by being convinced, as the great Continental schools have long been, that as imitation is the basis of both arts, the students in each should begin alike.

At the revival of art in Tuscany artists were artificers, and artificers were artists, in the strictest sense of the words. “It was not in the academy, but in the workshop, their genius was nurtured—the *arte degli orefici*.” “The goldsmith's craft was the chiefest school; hence came the best artists of all the three arts of architecture, painting, sculpture—Brunelleschi, Ghiberti, Orcagna, Luca della Robbia, Massolino, Ghirlandajo, Pollajuolo, Botticelli, Verrochio, Francia, Finiguerra, Andrea del Sarto, Baccio Bandinelli, Cellini, Salviati, Lioni, Vasari, and a host of inferior names, all were brought up to this good trade.¹ Painters were chiefly employed as decorators of houses and furniture, &c.” In all the associations of artists, trunkmakers, varnishers, saddlers, cutlers, and all workmen in wood or metal, whose crafts had any connexion with design, were admitted; and yet in England they are to be separated in education!

I think, therefore, that there is nothing “very erroneous in saying that the power of imitating natural objects artistically, ought to be the first requisite in the education of the ornamentist, or that the artistic imitation ought to begin by the human figure, since the mastery of this would render every other attainment comparatively easy.”²

To conclude, the error of the First Council of the London School of Design

¹ Murray's Hand Book to N. of Italy.

² Drawing Book, page 2.

was this;—viz., adopting the German instead of the French principle in educating the mechanic. The French begin by the figure and sound art—and the artisan thus educated carries sound art to ornament. The Germans begin by ornament, and make the figure and sound art the second step—and the Germans never recover the false taste of their education.

It is not yet too late to remedy this great mistake, by passing a law in the Council that every mechanic, as at Lyons, should be obliged to begin by the figure; and if this be not passed, I predict a corruption of taste in artisan and artist, which will throw the art into hideous confusion for years.

London, Nov. 7, 1842.

B. R. HAYDON.

ON THE RELATIVE PROPERTIES OF IRON,

Made by the use of Cold and Hot Air Blast, in the Smelting Furnace; lately read before the West-Riding Geological and Polytechnic Society.

By HENRY HARTOP, Civil Engineer and Mineral Surveyor.

In the early part of the year 1829, the use of hot air in the smelting furnace, for the manufacture of cast iron, was introduced at the Clyde Iron Works, near Glasgow, and at the fourth meeting of the British Association, held at Edinburgh in 1834, Dr. Clark gave an account of its success as follows:—

That in their previous operations with cold air, 8 tons, 1 cwt., 1 qr. of splint coal (made into coke, at a loss in weight of 55 per cent.), were required to make 1 ton of iron.

With the use of air heated to about 300° Fahrenheit, 5 tons, 3 cwt., 1 qr. of coal (in coke) produced a ton of iron, in addition to which, 8 cwt. of coals were used for heating the air.

In 1833, the temperature of the air used being 600° Fahrenheit, it was found that raw coal (not coked) might be used, which circumstance further reduced the quantity of coal required in the furnace to 2 tons, 5 cwt., 1 qr. per ton of iron made.

Not having been present at Edinburgh, on the Association's meeting, the following year, in Dublin, I stated that the case had not been correctly represented to Dr. Clark, inasmuch, as for some time previous to 1825, a saving in the coking operation had been made at every well-conducted iron work, by which a ton of iron could be made with 5 tons of splint coal in the furnace, when cold blast used, so that in reality a saving only took place by increasing the temperature of the air, so far as to enable them to use coal uncoked in the smelting furnace, from 5 tons to 2 tons 15 cwt., or 2 tons 5 cwt.

The account, therefore, as regards economy, by the use of hot air, will stand thus:—

	tons.	cwt.	s.	d.	£	s.	d.
Saving in coal used in the furnace	2	5	5	0	0	11	3
In Coker's Wages					0	2	3
					£0	13	6

A similar misrepresentation has also been made to Mr. Mushet, by reason of which he has been led into an error so far as to state in his most valuable work on iron and steel, pages 922, 923, that the materials used at the Milton Works in December 1834, with cold blast, were for each ton of iron made—

	tons.	cwt.	lb.
Coals	6	3	2
Ironstone	4	1	0
Limestone	0	13	0

At the same works in December 1836, with hot blast—

	tons.	cwt.	qrs.	lb.
Coals per ton of iron in the furnace	2	4	3	14
Ironstone	3	11	2	21
Iron Ore	0	0	1	0
Limestone	0	16	0	14

It is, however, well known, that on an average of the year through, previous to April, 1829, when cold blast was used at the Milton Works, the materials consumed were—

	tons.	cwt.	qrs.	lb.	
Coals in the furnace	4	16	0	0	} per ton of Iron made.
Ironstone do.	3	14	3	9	
Limestone do.	0	14	3	23	

And in comparing this with the make by hot air, in December 1836, (one

Against this may be set down—

A greater quantity of ironstone used					
per ton of iron made	0	3	8	6	0 1 3
Extra wear on ditto					0 3 6
Coal to heat the air used	0	8	2	0	0 0 10
					£0 5 7

Saving in materials by the use of

hot air, per ton of iron	0	7	11
--------------------------	---	---	----

To which saving may be added a further sum of 4s. 7d. per ton, for the greater quantity of iron produced from each furnace, when hot air and coals are used, making the total saving of 12s. 6d. per ton of pig iron.

But in 1835, the deterioration in the value of iron so made was about 17s. 6d. per ton, as I stated at Dublin, and at the present time, (March 1842,) I have no recantation to read so far as the above observations go.

In Dublin my observations on the deteriorated value of hot blast iron in the market of 17s. 6d. per ton were contradicted, but after seven more years of unceasing application, practised in the manufacture on a very large scale, of numerous experiments by indefatigable practical men of great ability, of the attention of learned professors of chemistry, mineralogy, and geology, together with the aid of that no inconsiderable engine the public press, the price of pig iron so made is 32s. 6d. per ton below that made by cold blast in the smelting furnaces.*

If you ask why iron so made is sold for 32s. 6d. less in the market, the answer is 1st, "its great weakness under impact, and therefore its total unfitness for most purposes in which the greatest weight of iron is used." 2nd. Its greater loss in remelting in the cupola of 2 cwt. per ton. 3rdly, The great irregularity in the contraction of castings when cooling, if made from hot blast iron, on which account many castings of different sizes are produced from the same pattern, causing great expense in their after fitting, or if this expense is not incurred, great defect in all machinery, &c., so made. 4th, Its unsoundness, that when made into castings require to be turned, bored, or planed, &c., on which occasions, if the surface operated upon is not defective on its entire area, a defect so considerable will show itself, probably when nearly finished, that both the casting and the great expense bestowed upon it will be thrown away, and in many such cases the expense of making the casting itself will be at least three times greater than even the present great difference in the value of the two kinds of iron.

I need not unnecessarily occupy your time further than by going more fully into the first of these points, the great weakness, under impact, of hot blast iron.

of the best months in the year for iron making,) an addition of 8 cwt. of coal being made for heating the air, the difference is truly so small as to be altogether unworthy of consideration, on taking into account the deteriorated value of the produce.

2 March 1842.	per ton.
Price of Scotch hot blast iron at Hull, (No. 1.)	£3 7 6
To which add for its general inferiority to Yorkshire iron	0 5 0
	3 12 6

Price of Yorkshire cold blast iron at Hull, (No. 1.)	5 5 0
--	-------

Difference in favour of cold blast iron generally	1 12 6
---	--------

* In Mr. Fairbairn's recent experiments, published in the Manchester Memoirs, the difference in this respect is very striking:—

Each bar being 1 in. square and 4 ft. 6 in. long between supports.

	Breaking weight.	Power to resist impact.
Oldberry cold blast iron	453lbs.	822lbs.
Oldberry hot do.	543	549
Using the same coal and ironstone,		
Elsecar cold do.	446	992
Milton hot do.	353	538
Working in the same mineral field in N. Wales,		
Ponkey cold do.	567	992
Plaskynaston hot do.	378	517

My attention was first called to the subject by observing great quantities of pig iron on the wharfs at the iron foundries and other places in this neighbourhood, very recently broken into pieces so short as to prevent the labourer piling them in cubical tiers in the usual manner, and on inquiry, I found that they were so broken by loading and reloading, and that they were made by the new process of using hot air in the furnace, greatly mis-called an improvement in the manufacture of cast iron. From these and other circumstances I thought it a duty due to the iron trade to call the attention of the public to it, and having mentioned the subject at the meeting of the British Association in Dublin, its importance was at once recognised, and a sum of money appropriated for making the needful experiments, which were carried into execution by Mr. Fairbairn, the highly intelligent and indefatigable engineer of Manchester; and I was very sorry to see in his report read at the Liverpool meeting, as well as in several conversations with me on the subject, to find that he had experienced great difficulty in ascertaining the composition of the irons experimented upon, in consequence of many of the manufacturers being unwilling to give information; added to this, it is well known that in more recent experiments, one of the strongest irons in Yorkshire has been placed in the scale of strength so much below other iron, long since known to be no stronger, both irons being made from the same coal and ironstone, a fence only parting the mineral fields of each work, that I am driven to the conclusion that the object of the experiments in question has in a great measure been defeated. There are, however, some experiments in them, which may not have been affected in their results by these circumstances, two of which I shall point out for your consideration.

The first will be that of iron from two works using the same materials.

Elsecar iron (cold blast) mean ratio of its strength	..	1000
Milton iron (hot blast) mean ratio of its strength	..	809
Elsecar iron mean ratio of power to resist impact	..	1000
Milton ditto ditto ditto ditto	..	858

In this case, however, the difference is much greater than appears on the face of these experiments, inasmuch as the specimens of pig iron from the Milton Works were made with the addition of a portion of the red hematite iron ore from Ulverston, for the express purpose of giving greater strength to that iron, as was invariably done many years for the purpose of making tin plate, and during the war for the casting of cannon.

The second circumstance is that where Mr. Fairbairn states that in a trial of 50 sorts of iron, of which each bar ⁴ of hot and cold blast iron were made of the same materials, and under the same circumstances.

Cold blast iron, with a load of 392 lb. increased the deflection in 108 days from 1.786 to 1.843 inches.

Hot blast iron ditto ditto 1.891 to 1.966 inches.

Cold blast iron with a load for 448 lb. continued to increase in deflection, and ultimately broke, after sustaining the weight 35 days.

All the hot blast iron bars broke in the act of loading them with the above weight of 448 lb.

Notwithstanding these and many similar facts brought out by the experiments in question, certain portions of them are constantly being quoted through the press for the purpose of proving that iron made by hot air is stronger than that produced by the use of cold air.

Contemporary with these experiments on a small scale, others of far greater importance have been going on; and we hear of hundreds of railway chairs, cast from iron made by the improved process, constantly breaking where tens only broke before, ⁵ of steam engines and other valuable machinery breaking in rapid succession, and in parts where, by regular work, they were never known to give way before the introduction of the improved iron—of the more respectable portion of mill-wrights being obliged to make new calculations, and a new stock of patterns, in order to lessen, as far as is in their power, the enormous losses and the great disappointment of their friends by such breakages. We hear of districts of coal masters and other prudent and

⁴ I take this to mean each pair of bars.

⁵ In a paper recently read before the Institution of Civil Engineers, Mr. Macneill states that on the Dublin and Drogheda Railway, where chairs were used made of hot blast iron from Scotland, the breakage was very great as compared with those on the South Eastern Railway, which were made of cold blast iron, and that in his opinion the latter would be cheaper than the former at an increased price of 4l. per ton.

humane proprietors of large establishments introducing clauses in their contracts for castings, stipulating that no hot blast iron shall be used therein; and at length the same has become common in contracts for gas and other pipes, which it has hitherto been usual to make of the most inferior quality of irons, it having been found that the sockets of some miles of piping have been broken off in one or two years after being laid down, in consequence of their having been made of hot blast iron.

There has, however, still more recently, been a series of experiments made, upon which a far greater dependence may be placed, inasmuch as the irons were all supplied in the regular way of business, without the makers knowing any such experiments were intended; and they were undertaken for the purpose of information only, to guide the founder and engineer who conducted the operations at his own establishment. The detail of these valuable trials by Mr. Todd, of Leeds, formed a paper read before this Society when last it met at Leeds; I need not therefore occupy your time with repeating them, and here, will only call your attention to a few of the results, for the purpose of more clearly explaining what I wish particularly to impress on your notice.⁶

With respect to the strength of bar iron made from hot blast pig iron, very few experiments have been made public that I am aware of; they are, however, of very great importance, because they were made with the greatest possible care, and regardless of expense, by manufacturers of the first eminence and ability for their private information. The irons were eight in number; the first set of bars were 2½ inches in diameter, made with cold blast scraps and hot blast respectively, all by Yorkshire manufacturers. The weight required to draw them asunder by a steady direct tension was not very variable, but when all were cut round to the same depth, for the purpose of being broken with the hammer, they required about the following blows to do so:—

						Blows
Cold blast iron	..	..	..	..	..	6
Scrap	..	..	..	..	..	3
Hot blast	..	..	..	..	..	1

The second and third set of bars you have now before you, the result of experiments on which stand thus:

	Diam. of bar.		Area of sec.		Blows required to break them with a 17lb. hammer.
	in.		where cut.		
Low Moor cold blast	..	2.66	..	3.976	.. 18
Bierley cold blast	..	2.75	..	4.430	.. 18
Milton hot blast	..	2.75	..	4.430	.. 3
					Blows required to break them with a 20lb. hammer.
Elsecar cold blast	..	2.58	..	3.976	.. 21
Milton hot blast	..	2.58	..	4.203	.. 1½
Made from the same materials.					

So that the proportionate resistance of hot blast wrought iron to impact is still less than that of cast iron. I need scarcely say, cold blast iron was ordered at probably 6l. per ton more than the hot blast iron might have been bought for.

I may here take leave to mention the circumstance of scrap iron being any thing now but what it was formerly, when its name and excellent quality were synonymous. In former times the importation of scraps from the con-

⁶ They took place from August, 1840, to February, 1841.

		Breaking weight	
		average	cwt. qr.
Bierley pig iron, No. 3, made with cold blast		25	2
Elsecar do. 3, do.		24	0
Low Moor do. 3, do.		23	2
Summerlee (Scotch) 3, hot blast		17	2
Level Staffordshire 3, do.		16	0
Mixed pig iron 3, 5 parts Low Moor, 1 part Elsecar		30	0
Mixed pig iron 3, 5 parts Bierley, 1 part Elsecar		33	0
Mixed pig iron 3, equal parts Bierley, Elsecar, Low Moor, Staffordshire, (Cylinder iron in the market,) and Level iron, also, Summerlee		20	2

tinient of Europe took place to a very considerable extent, all of which were manufactured in this country into bars, sheet's, &c.; and from the circumstance of these scraps, being all of charcoal iron, the bars, &c., so made, could not but deserve the good name they acquired and long maintained. The flow of scraps into England has, however, long since ceased, and the exportation from this country having become a considerable trade, it follows, of course, that scrap iron now must be made from our own scraps; and when it is remembered how small a proportion of good iron to bad has for many years been made here, bars, &c. manufactured from them cannot but be of very irregular and dubious quality, hence it is that the best scrap iron cuts so poor a figure when compared with a well made iron from known good minerals.

The remarks I have made are in reference to irons of known good quality, but I am ready, and have pleasure in admitting that the use of hot air has been of very great advantage at those iron works whose produce had not a first-rate name, by enabling their proprietors to make it at a less cost, without a proportionate deterioration in quality; and there are some few works whose iron, made with cold blast, was so bad, that any change could not be but for the better. There is also at present a strong impression that iron cannot be made with anthracite coal only, but with hot air, and that iron so made is better than any other. The goodness of its quality is, however, due to the great purity of that coal. But even here we are told, in a paper read before the Polytechnic Society of Cornwall, by a gentleman of great practical skill, that iron made with such proportions of anthracite coal and coke as enabled him to use cold blast, became much weaker on his using hot air, all other circumstances being the same.

My apology in troubling you so far must be in the importance of the subject, and the daily increasing importance to society of the strength of that material by which the locomotive power is applied that so rapidly conveys a very large portion of the human race both by land and sea. When we are about to purchase a horse which is to convey ourselves and families at the moderate rate of 8 or 10 miles an hour, with what inherent caution our first object is to examine his knees, to ascertain his safety! In the steam-engine we are prevented taking this precaution, and yet in travelling three times as fast, our risk is in very much greater proportion. Now in this fast travelling it must not be forgot that in the engines which convey us there are two cylinders, and at least 280 returns of the piston, and therefore there are 280 percussions each minute of 9,240lb. pressure in the power itself, and also the tires of about 42 wheels and axles in each train, passing over a joint of the rails every 5 yards of our journey, the percussions of which are very sensibly felt, with numberless others of minor effect, by which it will be at once seen of what inestimable importance it is that all iron used for such purposes should not only be strong, but be so under percussion; for I need only remind you that it is more than probable, should any one of the numerous parts give way, by any one of the many percussions they have to sustain, that an accident of the most calamitous nature would be the result.

With this view of the subject I may probably be excused, if I so far further trespass on your patience as at least to endeavour to point out a duty which the public only can perform for itself, namely, to take especial care that the needful protection is given to that class of iron makers whose first care it is to maintain its utmost strength, regardless of the expense of doing so. And in order that it may be understood how far such protection is required, the following statement should be made known. In the year 1830 the total quantity of pig iron made in Great Britain was about 653,500 tons. In 1840 the make had increased to 1,396,400 tons; and although the stock of pig iron at the latter date was very small, the price of No. 1 had declined since the use of hot air from 8*l*. 5*s*. in 1836, to 5*l*. 5*s*. per ton in 1842 for cold blast iron; and from 7*l*. 5*s*. to 3*l*. 12*s*. 6*d*. per ton for hot blast iron, * although the workmen's wages throughout that period were rather higher, which item forms nearly 75 per cent. of the cost, from which circumstance it has been very fairly concluded, that the price of the best pig iron made has been brought down at least 30*s*. per ton lower than it would otherwise have been

* I have been informed that No. 1 hot blast iron has been delivered in Leeds for 3*l*. 2*s*. 6*d*. per ton, the average of former years being 9*l*. 10*s*. per ton for No. 1 cold blast pig iron.

by the badness of trade generally, had not the use of hot air been introduced in its manufacture.

In addition to the observations I have already made on this subject, I may refer to the price current of the present day, and those who do so will see the price of cold blast pig iron in South Wales stand at 3*l*. 10*s*. per ton for No. 1; hot blast pig iron in the Clyde, 2*l*. 10*s*. per ton for No. 1; and, upon the whole, it seems this case may now be thus summed up, that—

The saving in the make of pig iron by the use of hot blast may	per ton.
(generally speaking) be	£0 12 6
Deteriorated value of such iron in the general market	1 0 0
Deteriorated value in the Yorkshire district	12 6
Deteriorated value of castings made of such iron, in the simple article of railway chairs, as reported to the Institution of Civil Engineers, on the 1st day of March last, by one of their own body, of the first eminence, and of very great experience in such matters	4 0 0
Deteriorated value of wrought iron when manufactured from pig iron so made, in the market	6 0 0

Indeed, of the last-named iron, engineers and intelligent manufacturers are agreed, and the experiments I have before referred to, show that 6*l*. per ton is far too little a deterioration for bar-iron of such a quality, and particularly when we reflect how very much bar (and other) iron has now to do with the personal safety of millions of our fellow-creatures.

Barnborough Hall, near Rotherham.

SHANNON IMPROVEMENTS.

Lieut. Col. Harry D. Jones, R. E., Shannon Commissioner, and Thomas Rhodes, Esq. Principal Engineer, were at Killaloe, on the 17th and 18th October, to witness the discharge of the river over that part of the weir which has been completed, owing to the active exertions of the contractor, Mr. W. Mackenzie, who has advanced the works at this station so rapidly, that they may be said to be fast approaching completion.

The weir forms the principal feature of the improvements at this station, having for its objects to modify and regulate the great rise of the annual floods, by giving greater freedom of discharge and making a consequent reduction in their altitude, at the same time preserving a sufficient depth of water for the navigation.

The weir, when finished, will be 1100 feet in length, of which 618 feet are now completed.

All things having been prepared, the dam which excluded the water from the weir while building, was broken about half-past 3 o'clock on Tuesday afternoon, under the immediate directions of the Commissioners' engineers, Thomas Rhodes and Thomas Barton, Esqrs. The water having been let into the space above the weir, began to flow over it about 5 o'clock, and though the quantity passing over at present is small, yet the effect was grand. It is calculated that during the flooded seasons there will be little more than three feet of water flowing over it, although, in seasons previous to the improvements, the floods have risen to a height of nine feet, thus showing a general reduction of six feet in the height of the flood waters, and proving with what effect the hand of science can grapple with this mighty element.

The above operation has opened the canal from Killaloe to Cussane, which had been closed for some weeks, and the communication is now complete from Limerick to our pierhead.

No accident of even the slightest description occurred, and the whole went off to the evident satisfaction of all present; the day being fine, the number of spectators were very considerable. The Lord Bishop was present at intervals during the day, and the spectacle was heightened by the presence of many beautiful ladies, (of whom our gay little town has certainly an unusual share,) together with many of the gentry from the surrounding districts.

The town and neighbourhood possess great interest, both from its natural beauty and its commercial character. We here see the imprint of the Dublin Steam Company, whose great and liberal exertions in the cause of commerce and navigation, under the masterly guidance of C. W. Williams, Esq., aided by the scientific intelligence of their agent, Joseph Clarke, Esq., and the indefatigable attention of Captain Tully, keeps the curling volume from the steamers' tube gracefully mixing with the beautiful outline of our mountains, while she bears along the noble Shannon the produce of our lands, our trade and fortune, and connects our interests with the world.

From the bridge the scene is one of exceeding beauty, and becomes enhanced by historical recollections, for while we here meet, upon the banks of Shannon, many of Ireland's fairest daughters, we see reflected in the bosom of its waters the beautiful hills where, eight centuries ago, dwelt the bravest and best of her sons—Kinkora's Prince, Clontarf's hero, the great and virtuous, the immortal Brian!

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

June 21.—(continued.)

"On some peculiar Changes in the Internal Structure of Iron, independent of, and subsequent to, the several processes of its manufacture." By Charles Hood, F.R.A.S., &c.

The singular and important changes in the structure of iron, which it is the object of this Paper to explain, are those which arise in the conversion of the quality of iron, known by the name of "red short iron," which is tough and fibrous, into the brittle and highly crystallized quality known by the name of "cold short iron." This change the author considers has never been attributed (as it ought to be) to the operation of any definite and ascertained law, but has generally, when observed, been supposed to arise from some accidental cause, and been considered as an isolated fact.

The fracture of railway axles, by which some of the most lamentable accidents have occurred, arises from this molecular change in the structure of iron, by which the axles lose a vast proportion of their strength.

The principal causes which produce this change are percussion, heat, and magnetism, and the author traces through a great number of practical cases of ordinary occurrence the joint, as well as the separate effect of these three causes; showing that the rapidity of the change is proportional to the combined action of these several causes, and that in some cases where all the three causes are in operation at the same time, the change of structure is almost instantaneous; while in other cases, where this united operation does not occur, the change is extremely slow, extending over several years before it becomes sensible. Among the examples given, and of which the causes are explained, are the conversion by means of heat, as in the case of wrought-iron furnace-bars, and other analogous cases, particularly when any vapour is present: the operation of the tilt hammer in the planishing of iron, by which both vibration and magnetism of the bar is produced, when the temperature is within a certain limit, beyond which limit the bar loses its magnetic power, and no crystallization occurs; and the instance of piston-rods and other cases, where from any accidental circumstance a peculiar jar or vibration has been given to particular parts. The effect of the continual jar or vibration upon the axles of common road carriages is a case of the opposite kind, where, notwithstanding the continual vibration, this molecular change does not take place *when the axle is insulated from the effects of magnetism*. In railway axles, however, the case is very different. The rapid rotation of the axle produces powerful magnetic action, while the friction causes much heat; and these effects, added to the constant percussion which is produced by the peculiar motion of railway wheels, causes the crystallization to be produced with extreme rapidity; the effect being probably further increased in the axles of locomotive engines by the magnetising power of the electricity generated by the effluent steam. The crystallized structure being the natural condition of iron, as well as of several other metals, the author considers that in these changes we observe a constant effort to return from the artificial to the natural and primal condition of the metal, and the conclusion arrived at is, that this crystallization is not necessarily dependent upon time for its development, but is determined by other circumstances of which the principal is undoubtedly vibration: that heat, although it assists, is not essential to it, but that magnetism, whether induced by percussion or otherwise, is an essential accompaniment of the phenomena. The paper concludes by pointing out the increased effects likely to result from the rigidity of the springs, the looseness of the brasses, and other causes which increase the vibration on the axles of railway carriages.

Several samples of broken railway axles were exhibited; some of them being cut from different parts of the same axles, showed that at the journals, where the vibration was the most intense, the crystallization was increased to a great extent beyond what occurred in other parts of the same axle.

Remarks.—Mr. Moreland had frequently noticed that pins for chains, and pump-rods, although made of the best iron, would, if subjected to concussion, after a certain time break suddenly, and that the fracture would exhibit a large crystallized texture. This was also frequently observed in the broken axles of road-carriages, although they were generally made of iron of the finest quality.

Mr. E. Woods had observed the crystallized fracture in all the broken axles on railways which he had seen.

Mr. Hood exhibited some specimens of broken axles, all of which showed a large crystallized fracture: he believed that the iron from which the majority of them had been made was of the best quality, and in the parts not immediately subjected to concussion the fracture was quite different. One of them had been in use only three months, and had become so brittle that, on attempting to break it, it jarred off at the shoulder of the journal, although an incision was made all round at the spot where it was intended to be broken.

Mr. York would account for the tendency of the axles to break at the journal, by that part being subjected during the process of forging to more hammering than the body.

Mr. Hood agreed that such might be the case, but he conceived that it was more probably produced by cold hammering. He had taken a sample from the body of a broken cranked axle, from the Grand Junction Railway, the iron of which was evidently of the best quality, but at the point of frac-

ture, which was certainly at that part where it had been most hammered, the fracture presented a large crystallized texture.

A large anchor, which had been in store for more than a century, at Woolwich Dock-yard, and was supposed to be made of extremely good iron, had been recently tested as an experiment, and had broken instantly with a comparatively small strain; the fracture presented very large crystals: in this case he believed the length of time which the anchor had remained in the same position had produced the same effects as magnetism and vibration.

Mr. Lowe stated that at the gas-works under his direction wrought-iron fire-bars, although more expensive, were generally preferred; a pan of water was kept beneath them, the steam from which would speedily cause them to become magnetic: he had frequently seen these bars, when thrown down, break into three pieces with a large crystallized fracture.

Mr. Miller had frequently seen in manufactories, that when the smiths had forged parts of engine-work which from their intricate forms had required to be much hammered, the ends were jarred off while they were being worked upon. He instanced particularly the side rods of the engine for the "Lord Melville" steamer, of which, while shutting up the middle, one of the ends of each rod was jarred off, and presented large crystals in the fracture; being well assured of the good quality of the iron in the rods, he had the same ends welded on again, and although the circumstance had occurred 20 years since, they were still at work, and had not shown any symptom of weakness. It must be evident that in this case, the fracture and the crystallized appearance of the metal must have been produced by the cold hammering to which it had been subjected.

Mr. York agreed with Mr. Hood in the fact of a change taking place in the texture of the iron, but he was of opinion that it more frequently occurred during than after manipulation; he alluded more particularly to railway axles, in which he believed the injury to be done by the cold hammering or planishing after they were faggoted; he had frequently seen one end of an axle fall off while the other was being hammered: in all such cases, and those of accidental breakage, such as recently occurred on the Versailles Railway, and in other places, the fracture always presented a crystallized appearance.

He then exhibited and described a railway axle, which he stated to possess the combined advantages of rigidity and toughness, and avoiding entirely the crystallization of the iron during the process of manufacture; this he described to be effected by maintaining the axle in a hollow state during the whole operation of hammering, thereby avoiding the vibration and concussion, to which cause he attributed the crystallization of the iron in solid axles, being of opinion that the repeated blows of the hammer on a solid mass, particularly during the process of "planishing," were the chief, if not the only cause of the ductile quality of the iron being destroyed. He stated, that he had made numerous experiments for the purpose of ascertaining this fact, and in every instance when the axle was sound, the iron presented the same crystallized fracture, although the bars, previous to their being welded together, were of the most fibrous quality, but if the axle was not quite sound, and the bars not perfectly welded to the centre, then the fracture was somewhat fibrous, the axle being partially hollow and thereby avoiding the vibration to a considerable extent. This fact suggested to him the propriety of keeping the axle hollow; and the mode of manufacture he described to be by taking two dish half-cylindrical bars of iron, of the entire length of the axle, putting them together and welding them under a hammer in swages, by which means the particles are not driven asunder by the heavy blows and the axle of faggot lengthened, but are driven together and towards the centre. The axles produced by this means, he stated to be as perfectly ductile as the bars in the first instance. A further advantage, he stated to consist, in being able to make half the whole length of the axle at one heat, thereby avoiding to a considerable extent the danger of burning the iron by repeatedly heating it; the iron in the axle he described, as being a uniform cylinder in thickness, and consequently requiring a uniform heat, whereas the external bars of a faggot for a common axle were liable to be burnt, before the centre was heated to a welding state. The diameter of the hollow axle was increased from 3½ in. (the general size of a solid axle) to 4 in. in order to give a proper degree of rigidity, but without increasing the weight.

The usual proof to which solid railway axles were subjected, was by allowing a weight of 6 cwt. to fall upon them from a height of 9 ft.; with that force they were frequently broken at the second blow, and sometimes by the first—he had tried some of the hollow axles, by letting fall upon them a weight of 10 cwt. from a height of 15 ft., without breaking one of them.

Mr. Simpson expressed the obligation of the Institution to Mr. Hood, for bringing before the meeting such an interesting communication, upon a subject which it is of the utmost importance to railways, should be carefully examined. It was to be regretted, that the late period of the Session had prevented the attendance of those members whose attention had been more particularly directed to railways; but on the renewal of the subject next Session, upon the production of the report upon the projected experiments, promised by Mr. Hood, a very useful discussion might be anticipated.

June 28.—The President in the Chair.

"An Account of the Bridge over the Thames, at Kingston, Surrey." By John Brannis Birch, Grad. Inst. C. E.

Previous to the year 1828, when the present bridge was opened to the

public, the communication between the town of Kingston-upon-Thames in Surrey, and the hamlet of Hampton-wick in Middlesex, was carried on by an old and inconvenient wooden bridge, which was so dilapidated that any attempt to put it into a substantial condition for the service of the public, would have been equivalent to an entire rebuilding of the structure.

The corporation of Kingston, therefore, resolved upon erecting a new bridge, on a design by Mr. Lapidge, their architect, and in the year 1825 obtained an act of Parliament, granting them the powers necessary for that purpose.

The trustees appointed under the Act applied to the Exchequer Bill Loan Commissioners for pecuniary assistance to the amount of £45,000, but the application was not entertained until the working drawings, specification, &c. had been submitted to their engineer—the late Mr. Telford, when he gave the following opinion:—"Having carefully inspected all the working drawings, I consider it only justice to Mr. Lapidge to say, that they are very complete and do credit to his judgment and assiduity; and as the blue clay has been found quite across the bed of the river, I am of opinion that with the precautions provided in the working drawings and specification, that the work is very practicable, and if well executed will prove a substantial and useful edifice." He also said, "I have gone through the detailed estimates, and compared the same with the proposal accepted by the corporation, and am satisfied that the works may be properly executed for the sum therein mentioned, viz., £31,300;" and he stated "the amount of the general estimate including the above sum—the expense of houses and ground—the flood-arches and roads of approach, &c. to be £47,457."

Upon receipt of this report, the Commissioners consented to make the required loan, but it being found that the Act limited the amount to be raised to £40,000, alterations in the structure were suggested by Mr. Lapidge, which received Mr. Telford's approval, and the works were commenced on the reduced scale.

The bridge is of Grecian architecture and consists of five elliptical arches; it is constructed chiefly of brick, with ashlar facing. The abutments are terminated by towers, and the structure is surmounted by a cornice and balustrade, with galleries projecting over the piers. The span of the centre arch is 60 ft., with a versed sine of 19 ft.; the side arches are 56 ft. and 52 ft. span, and 18 ft. 3 in. and 16 ft. 6 in. rise, respectively. The highest flood rises 6 ft. above the springing line, and the lowest summer level is about the same distance below it. The foundations are all laid upon the substratum of blue clay. The length of the bridge is 382 ft. to the extremes of the abutments, and the width between the balustrades is 25 ft. The proportion of the piers to the span of the arches is about $\frac{1}{4}$ th. The roadway is formed at an inclination of 1 in 40.

The author then describes fully the construction of the abutments, piers, arches, and the superstructure. The work occupied about 2½ years to the completion, the first stone having been laid on the 7th of November, 1825, and the bridge opened in form on the 17th of July, 1828.

On the completion, Mr. Telford again made a report to the Exchequer Bill Loan Commissioners in these terms:—"With Mr. Lapidge, I examined the whole of the bridge and approaches, and taking it for granted that the foundations of the piers and abutments, which are under water, and which I had no opportunity of inspecting while in progress, are according to the working drawings, all the other parts are found in a very perfect state, executed in a workman-like manner."

The bridge has in every respect answered the object for which it was intended, and it has justified the good opinion Mr. Telford originally formed of it.

During the 14 years which have elapsed since its erection, it has required none other than the most trifling repairs, and the expectations of the trustees have been realized by the tolls having paid the allotted portion of the principal, up to the present time, as well as the interest of the money borrowed for its execution, and the cost of it did not exceed the amount of the estimate.

The communication was accompanied by seven remarkably well-executed drawings, showing accurately all the details of the construction, and the paper contained all the quantities of metals in the work, together with Mr. Telford's reports upon it, with other documents of interest.

"Description of the Harbour of Port Talbot (Glamorganshire)." By Henry Robinson Palmer, V. P. Inst. C. E.

The harbour described in this communication is situated upon the outfall of the river Avon, on the eastern shore of Swansea Bay. The adjacent mountainous district terminates abruptly at about half a mile from the shore, in a tract of marshy land, for the most part composed of sand, with detached beds of clay and peat of various thickness, at about 10 ft. below the surface.

The river, which, at its issue from its rocky channel, had been diverted from its course by accumulations of sand, nearly at right angles with its point of discharge into the sea, would appear at some period to have had a direct channel thither. It has been the object of the author, by whom the works were designed and executed, to restore this obvious course for the land water, and by means of embankments, to convert into a dock that portion of the old channel which extends through the marshes. A new channel has also been formed from the outfall to a convenient part of the dock, with a lock 48 ft. in width for the passage of vessels.

As the works were undertaken by a few private individuals, every proper economy was enjoined; and in order to diminish the expense of excavating by manual labour, a channel of 100 ft. wide and a mile in length, Mr. John Vigurs (whose extensive tin-plate and copper works are situated in the adjoining valley) proposed that the new channel should be formed by the force of the land floods, which descend with great impetuosity. A trench of 20 ft. wide by 10 ft. deep, was therefore cut in the line of the proposed channel; and a few days after it was finished, a heavy land flood descending from the mountains rushed through it, carrying out to sea from the sides and bottom of the trench an immense quantity of the soil. Every succeeding flood increased the size of the trench, and by judicious guidance of this natural excavator, the channel was formed of the requisite dimensions; and it is now generally kept clear from accumulation by the land floods, but in dry seasons by the sluices in the lock-gates. The bed of the channel is stated to form a regular inclined plane of more than a mile in length, free from a shoal or any other impediment.

The confluence of the two channels has been rendered permanent, by a pier of copper slag, with an active slope of 5 to 1. When finished, this pier will extend full half a mile in length.

The paper then describes generally the ordinary modes of construction adopted in the works, and more particularly the lock, the sill of which is 23 ft. below the level of an ordinary spring tide: the coping is 2 ft. above that level, and the gates are 25 ft. 6 in. high.

The fabric of the lock is composed of hard silicious sandstone, cemented with blue lias lime water. The ashlar work of the walls is 4 ft. in thickness, with counterforts, and the spaces between them are filled with rubble, grouted with lime and sand. The whole thickness of the walls may therefore be taken at 8 ft., excepting at their bases, where they are 10 ft. The walls rest in part upon an inverted arch, 3 ft. in thickness, and the whole mass, including the invert, rests upon a concrete of large and small rubble.

The harbour is stated to be in immediate connexion with extensive copper and tin-plate works, and also with a great extent of coal-beds bordering the valley of the Avon, and the trade is rapidly increasing, its position in the Bristol Channel being highly favourable to a foreign trade.

A plan of the harbour, with the streams and channels, and a transverse section of the lock accompanied the paper.

"Description of the Calder Viaduct, on the Wishaw and Coltness Railway, with the Specifications, Estimates, and a series of Experiments to ascertain the Deflection of two of the Strutted Beams." By John Macneill, M. Inst. C. E.

When first the author was called upon to carry out the extension of the Wishaw and Coltness Railway, he found that the funds for that purpose were very limited, and that it was necessary to construct the works in the cheapest manner possible. To accomplish this it was necessary to design and lay out a single line of railway, which would be sufficient to carry on the trade by H. P., but if possible, and consistently with limited funds, to construct the viaduct over the valley of the Calder (the principal work on the railway) in such a manner as to be able to widen it hereafter, and to make it suitable for locomotive power, in the event of the trade being increased, or of the railway forming a part of the great line of communication between England and the West of Scotland. Having these objects in view, and being so restricted in funds, he was obliged to lay out the works in the first instance, very differently from what he otherwise would have done, if there had been ample funds.

The valley of the Calder, which the railway had to cross, was nearly half a mile in length, and the elevation of the line over the surface of the ground, varied from 50 to 130 ft. The first intention was to construct a viaduct, 480 ft. in length, of stone arches, 60 ft. span and 12 ft. wide between the parapets; but as this mode of construction would have been the cause of much expense, when it became necessary to widen the viaduct for a double line of railway, and would also have involved an embankment of nearly 60 ft. in height, composed of clay and marl, which was considered unsafe and likely to slip, an effect which subsequent experience on other portions of the line, has since fully proved would have been the case; it was determined to extend the viaduct to about 1200 ft. in length, and to construct it of timber resting on stone piers, which allowed the means of widening and strengthening it hereafter, without stopping the trade or incurring more expense than would have been necessary in the first instance, if built to the full dimensions.

The piers and abutments are built hollow, of grey freestone from the adjoining quarry of Dalziel; the trussed wooden beams rest in metal sockets, and the springing plates are laid, for supporting the under arches of bent timbers, which are now in progress of construction, to render the viaduct capable of supporting safely the weight of locomotives and heavier trains than now pass along it by H. P. The usual load for horses is 4 wagons, each weighing 1½ ton, and carrying 3½ tons of coal; there are frequently 3 of these trains in a single arch of the viaduct at the same time, and 30 loaded wagons weighing 120 tons exclusive of the engine and tender, have frequently been taken over; on one occasion a train consisting of 65 loaded wagons of 4 tons each, making a gross load (including the engine and tender) of 279 tons was taken over the viaduct, but the usual load is restricted to 30 tons, until the under arches are fixed.

The details of the construction of the general work are then given, and

the total cost of the single width is stated to be about £15,000; this sum includes the metal castings for the future widening, and when the strengthening and widening of the whole will be completed the total cost will not exceed £25,000, which is stated to be a low price for a viaduct of 1200 ft. long, and varying from 50 to 130 ft. in height.

A description is then given of the experiments upon the deflection of a trussed beam. Two stone piers were erected 100 ft. apart, with metal caps and sockets built into them; two beams were laid and strapped together and the struts fixed, precisely as they would have been in the bridge; along each side of these beams, but quite unconnected with them, posts are driven in the ground, to which a horizontal beam was attached; six rods of deal, carefully divided into inches and tenths, were then screwed to the outside faces of the beams. The beams were, in the first instance, brought as near as possible to a horizontal line, by means of a spirit level, and the zero points on the rods made to correspond with a fixed line on the horizontal bar. When the beams were loaded, and the deflection from the original level took place, it was marked by the divisions on the index rods, which being firmly screwed to the beams rose or fell with them, and showed the quantity of deflection as marked by the line on the horizontal bar; after each load was put on the beams, it was allowed to remain an hour or two before the deflection was measured, and after the load was taken off, the deflection was again measured at an interval of some hours to ascertain the permanent set, before another load was put on. The load made use of was railway bars; they were distributed over the beams in various situations, and in various quantities, varying from 1 to 60 tons; the results of which are stated in a series of elaborate tables: and a large collection of diagrams show the situation and form of the load and the space covered at each experiment. By examining these diagrams, the situation of the load, its weight, and the deflection caused by it, will be at once seen; the results of these weights are given in the tables in feet and decimals, which will be more satisfactory than the diagrams alone would be, to those who may wish to make any calculation, or to form a practical rule upon them for their own guidance.

The appendix contains the specifications for all the artificers' work, with the dimensions of the several parts and the priced estimates:—the drawings accompanying the paper were executed by Mr. Macmillan's assistant, George Ellis, Assoc. Inst. C. E.

"Description of the mode adopted for sinking a Well, at Messrs. Truman, Hanbury, Buxton, and Co.'s Brewery." By Robert Davison, M. Inst. C.E.

The author commences this communication, by stating that one of the principal objects of the brewers, is to obtain a constant supply of water at a low temperature, for the purpose of cooling the worts, particularly during the summer months. The quantity of water to be obtained from the land-springs has (he says) been represented as not to be depended upon; this would probably be correct, if required, as frequently proposed, for the supply of all the wants of a city, but if a well is properly sunk, there can be no doubt of obtaining a supply of 80 to 100 gallons per minute.

With regard to the quantity of water obtainable from the chalk stratum, the author believes it to be more precarious, for while instances occur occasionally, where a considerable opening is found in the chalk and a plentiful supply is obtained; the cases it is believed are as frequent, where fissures are not met with and a failure ensues.

He then proceeds to give a narrative of the facts which occurred during the progress of an attempt to sink a cast-iron cylinder from the surface down to the chalk, a depth of about 200 ft., intending to admit the springs at the different levels, as might be considered most advisable.

The well was commenced in the middle of a landspring well 16 ft. diameter, and in order to avoid the usual inconveniences of pumping and excavating, Mr. Clark of Tottenham performed a large part of the work with the "Miser" instead of by the usual methods of well-sinking.

The landspring well was drained January 25, 1839, and the excavation of a well 11 ft. diameter was commenced; this was carried down of a clear diameter of 8 ft. 6 in. inside the brick steining, and when it had arrived at the depth of 115 ft. 3 in., the first cast-iron cylinder was lowered, and others were gradually added, shutting out the springs as they were passed, until April 3, when, at the depth of 135 ft., in a bed of yellow clay and pebbles, the water overpowered the excavators, and after trying many methods of continuing the excavation, the use of the "miser" was resorted to, when the cylinders had gone down to 144 ft. On the 11th of May the oyster bed was reached, at 163 ft. depth; and after some deliberation, it was resolved to continue sinking down to the chalk. For seven days the men were employed in "jumping" a heavy obisel bar to break through the hard rocky crust of this oyster bed; at length between the 25th and 27th of May the cylinders suddenly sunk 5 ft. 6 in.; the misering was continued until the depth of 189 ft. 10 in. was attained, and the cylinders were found to be completely fixed. A pressure of nearly 100 tons applied by powerful screws was tried without producing any effect; it was therefore determined to fill all the space between the steining and the exterior of the cylinder with concrete, although a portion of the steining was discovered to have given way; it was supposed that the cylinders would have been held up by the pressure against the steining and the earth; the pump-work was therefore fixed, and after a time the pumping commenced; on the 21st October, after no more

than the usual pumping (the water generally containing sandy sediment), it was observed that the pavement round the well had given way; the machinery was stopped, and immediately there occurred a rumbling noise within the cylinders which lasted probably 4 or 5 minutes; on examination, it was found that the cylinders had sunk 4 inches, the main girders across the top were broken, and on sounding the well it was discovered that an extensive "blow" of sand had taken place, and filled the bottom of the well for nearly 28 ft.; this was cleared out by misering, and after recommencing pumping for some time, on the 14th December a separation of the cylinders about 2½ in. wide was discovered at about 73 ft. from the surface. Mr. J. Braithwaite and Mr. J. Simpson were consulted as to the best method of proceeding; the former was of opinion that there was such a subsidence behind the cylinders, as would endanger the safety of the surrounding buildings. The latter did not take so serious a view of the matter; but he suggested the sinking of an internal cylinder, if the original one could not be forced down.

After this examination, a portion of one of the cylinders was cut away at 72 ft. from the surface, where the soft part of the clay commenced, and a dome was constructed with brick and cement all round the exterior of the cylinder, with the intention of supporting the brick steining and struts above, and also to carry off the water and prevent its softening the clay and the concrete.

On the 18th of March, 1840, an internal cylinder of 2 ft. diameter was lowered, within the original cylinder, and continued sinking until it reached the chalk, into which it was driven 4 ft.; the space between the large and small cylinders was then filled in with granite paving stones from 5 ft. in depth, and then with smaller stones, broken bricks, &c. mixed with hydraulic cement, to the depth of 25 ft., thus forming an effectual barrier against any future "blow" of sand from the original bottom of the well.

After all was imagined to be secure and the pumping had recommenced, a second separation to the extent of 4 in. was discovered in the cylinder; the gap thus formed was first filled in completely with wooden wedges, and a cast-iron cap was afterwards bolted within side. The well was then drained, and 400 holes ½ in. diameter were drilled in the cylinder, immediately beneath the oyster bed, to admit the water from that level. It was ascertained also by experiment, that the quantity of water obtained from the 2 ft. bore in the chalk, was about 22 gallons per minute; the bore was then continued for a depth of 200 ft. making the total depth of the well and the bore from the surface, nearly 400 ft., when a supply of water was obtained of 33 gallons per minute; some of the joints of the cylinders were then picked out, to admit the water, and from all the sources combined, the quantity of water obtained, was about 81 gallons per minute, or 135 barrels per hour; that is, 55 barrels from the chalk spring and 80 barrels from the sand-spring per hour.

The cost of the well and the bore was £4444, to which must be added the expense of a 12-horse steam-engine and pumps £1351, making a total cost of £5795.

Appended to the paper is the report of Mr. James Simpson, which gives a very clear account of the state in which he found the well, and the remedies which he suggested, for the accidents which had occurred.

It is illustrated by two drawings, showing in detail a vertical section of the well, with all the pumps and machinery, and also the tools used in the excavation and the bore.

"Description of a Self-acting Signal for Railways." By Charles Berwick Curtis, (of Acton,) Assoc. Inst. C. E.

The object of this invention is, that notice shall be given by a marked signal, both by day and night, to the trains on the railway, that they may proceed with safety, and to regulate their speed. The signal being worked by machinery, the policemen would not be required, as at present, to remain on one spot, but could extend their sphere of inspection; and thus, by fixing the apparatus at given intervals along the line, the passage of the trains could be arranged with such precision as to render collision less frequent.

The apparatus consists of a round signal, composed of glass, the upper third part red, and the remainder green, descending into view from a casing of three colours, such as black, green, and red, in equal divisions: upon the signal is a white plate, which projects in front of and through a slit in the casing; and in order that the signal may be used by night as well as by day, a lamp is placed immediately beneath the centre of the casing.

On the near side of the rail, at a suitable distance, and at a proper height to be cleared by the steps of the carriages, is fixed a trigger, which is attached to a horizontal shaft revolving on bearings, with a counterweight, and these are connected by suitable shafts and levers with the signal-field. When an engine passes and depresses the trigger, the signal-field is released, and falls below the casing; by this means the machinery is set in action, and in a given time (which is regulated by clock-work) gradually raises the signal-field up again, within the casing, indicating by the coincidence of the coloured compartments of the casing with those of the signal, the length of time which has elapsed since the trigger was depressed. When the signal has returned entirely into the case, the apparatus has resumed its original state ready to be again acted upon.

Several ingenious modifications of the apparatus are described; and it is stated that the signals which have been at work for a considerable period at the London and Birmingham and Great Western Railways, have fully answered

Fig. 1.

Fig. 2.

Fig. 3.

the expectations entertained of their efficacy. Detailed drawings of the signals and machinery accompany the paper.

The following description of the apparatus we have obtained from Mr. Curtis, which will more fully explain his ingenious inventions than the preceding brief minutes of the Institution.

Fig. 1, is a front view and section of the apparatus, with a round signal field descending into view from a boxing. The arrangement of the contrivance is as follows:—By the left or “near” side of the Rail, at a suitable distance, and at a proper height to be cleared by the steps, and other projections of the engines or carriages, is fixed a trigger or camb, to the end of a horizontal shaft, revolving on bearings, upon a sleeper of wood or stone, properly secured, and is furnished with a counterweight. The trigger is made to the radius of 1 ft. 6 in., of strong wrought iron, and for the purpose of securing a smooth surface, is covered with a plate of brass; at the other end of the shaft is a double joint, from which rises an upright rod, secured by guides, to the wall or framework; the upright rod terminates in an oblique link and bent neck, working in a bearing, at the point of which neck is a hammer head, which, as the trigger by the side of the rail is depressed, is forced inwards, and drawn back again by the counterweight of the horizontal shaft on which the trigger is fixed.

The signal field is fixed on a lever, having its fulcrum or bearing at about one-sixth of its length from the other end, and is sustained out of sight, that is, behind the boxing, by pins placed equidistant at three points upon a ring fixed upon the centre arbor of wheelwork, which centre arbor is immediately opposite to the hammer head of the bent neck of the upright rod, and receives its blow. The centre arbor being forced in, and thus withdrawing the pin from holding the end of the signal lever, releases it, and it falls by its own weight. The wheelwork of which the motion is sustained by a weight, and which when holding the signal lever is kept motionless, is now set in action, and the ring having the three pins revolves, and the pin next in rotation travels towards the end of the lever, consuming three minutes and a half before it comes in contact; when in contact it gradually depresses the end of the lever, and raises the signal; the white plate now leaves the red compartment, and passes on the green, and the upper limb of the field is withdrawn from view, and continues to rise with the white plate, in the green compartment, till it is wholly out of sight, and the white plate appears on the black compartment, and arrives at its resting place, whereby the wheelwork is stopped.

At night the lamp being lighted, the colours of the glass indicate the signal according to the same periods, viz.: three minutes and a half red, and six minutes and a half green light, and afterwards exhibiting the white light.

The wheelwork is so arranged that 40 trains may act upon it for one winding up. It comprises a wheel working into that attached to the barrel, the arbor of which wheel is elongated and made square, and carries the ring upon which the three equidistant pins are placed, which ring is fixed on a *boss*, made to slide backwards and forwards upon the square elongated end of the arbor, furnished at the back, or between the ring and the face of the frame of the wheelwork, with a spiral spring to drive the ring with the three pins back to its working position, when forced in by the hammer; the only other wheels necessary are those leading to the escapement, which consist of a simple balance wheel. A striker must be attached to the engines or tenders, made of ash, or other long grained wood, 4 ft. long, and 6 in. wide, cut lengthways of the grain, and inclining to the extent of one-third the

length from each end towards the centre, the intermediate one-third being left straight, and so fitted that it shall depress the camb or trigger 2 in.

Fig. 2, is another apparatus, with a fan of two colours, one-third red, and two-thirds green, enclosed within a suitable boxing, having a triangular opening. The wheelwork and action are precisely the same. The train passing and acting on the trigger, the fan falls and presents its red portion in the opening, and on being drawn back its green portion, and being at the extremities furnished with glass of those colours to correspond, so as to pass before a lamp, gives the colour signals at night. The fan signal must be erected upon a pedestal, at a convenient distance from the side of the rail, and high enough to insure its being visible to the drivers of engines.

Fig. 3, is the third mode of arrangement, that of the signal mast, which is made to turn one quarter, thereby exhibiting a change of figure.

The machinery applied to this is of the same nature as the foregoing, but placed horizontal instead of vertical, and in place of a lever being released from the pins, as in *them*, a sector, with teeth working on a bearing or gudgeon into a segment attached to the mast, is employed. A weight and line is fixed to the mast, which upon one of the pins being released from its hold, as in the other arrangements, draws the mast round one quarter, exhibiting thereby the signal to indicate “stop” or “danger;” three minutes and a half are consumed in the approach of the pin to the end of the sector, and six minutes and a half from the time the pin comes in contact, till it has drawn the mast back again, and restored the signal of “safety.” A lamp is fixed on a stationary standard, but is enclosed in a three-sided lantern, with coloured glass, red, green, and white lantern traversing with the mast, in front of the lamp, showing thereby the colours according to the position of the mast: red, green, or white.

One apparatus is placed at the south entrance of the Primrose Hill tunnel, and an engine fitted for the purpose of operating upon it, which it has done since the autumn of last year, and still continues to do daily with the 3 o’clock train. And on the Great Western Railway the *three distinct* forms, above described, have been erected at the Paddington Terminus.

END OF THE PROCEEDINGS OF THE SESSION, 1842.

The Institution will resume their Meetings on Tuesday, the 10th of January next.

YORKSHIRE ARCHITECTURAL SOCIETY.

First Report, read at the General Public Meeting, October 7th, 1842.

A REPORT of the past, as connected with a society which awaits its formal constitution at the present meeting, must of course be meagre; but the members have a right to know how the Yorkshire Architectural Society originated, with what support, with what field of usefulness before it, and with what prospects of success.

When several persons had already expressed a wish that in this county, which presents perhaps the best field of architectural study in the kingdom, an Architectural Society should be formed, several of the clergy of the dioceses of York and Ripon having been invited to attend, a meeting was held at Leeds, the Rev. the Vicar in the chair, on the 26th of July last. At this meeting, with the approbation of many who were absent, and with the united

care of those present, provisional rules were framed, and officers *pro tempore* appointed, and it was determined that all the parochial clergy in the county should be invited to join the society in its earliest stage. That the greatest deference might be paid to authority, His Grace the Archbishop of York, and His Lordship the Bishop of Ripon were requested to extend their patronage to the proposed society, and the Lords Lieutenant of the three Ridings were requested to accept the office of Presidents. The sanction of these great names was most kindly afforded; and we were also permitted to number among our Vice-presidents the Archdeacons of most of the archdeaconries within the two dioceses, and many noblemen and gentlemen whose names must give strength to our cause. Of ordinary members we have already, and before any public meeting, more than 300 names on our list; and many of those who were among the first to give their names to the society, have expressed most strongly their opinion, evidently not newly formed, that such a society was much needed.

With regard to the objects of the society, they are stated briefly but comprehensively in the second resolution passed at the preliminary meeting, as follows:—

"That the objects of the society be to promote the study of ecclesiastical architecture, antiquities, and design, the restoration of mutilated remains, and of churches or parts of churches which may have been desecrated, within the county of York; and to improve, as far as may be within its province, the character of ecclesiastical edifices to be erected in future."

If we may be allowed to expand this resolution, we may say that whatever tends to the knowledge of the principles or details of church architecture, as it was practised in the middle ages; and whatever may suggest any improvements in the general style of ecclesiastical edifices in the present day; that whatever may tend to explode the anachronisms and other solecisms in church building now so common; that whatever may serve to extend a taste for the higher branches of the art, and to inculcate reverence for it in its most sacred applications; that whatever may indirectly encourage, or directly effect the restoration to their pristine beauty, or to their sacred use, of any ecclesiastical remains, or any part of the essential furniture of the sanctuary; whatever may come under any of these heads, the Yorkshire Architectural Society proposes to itself as the scope of its operations. How far it may be obliged to do this indirectly only by suitable publications, and by suggesting an object of study to its members, and those who may interest themselves in its proceedings, and how far directly, by rendering assistance, pecuniary or otherwise, to those who will gladly avail themselves of its aid in the repairs or construction of sacred edifices which Providence has committed to their charge, must of course depend on the resources which the society may have at its disposal, from the number of its members, or the liberality of more wealthy supporters.

That some stimulus, of some kind or other, to cultivate a better style of church building, and some direction of the public taste in matters even of the minutest detail, and most trifling repairs, is needed, must be clear to every one who will take the trouble to run over the churches, ancient or modern, within a drive of his home.

With regard to new churches, there is scarcely a populous district in the kingdom which does not possess one of the churches built in pursuance of the "Million act," as it is called; a huge cumbersome erection, Gothic in its details, without any principle, or if following any principle at all, probably Grecian in its proportions; in size beyond the compass of most voices, and in arrangement destructive of all articulate sound. The floor is divided between pews and benches, making an invidious distinction between Christ's poor, and the world's rich, and galleries destroy whatever there would have been of ecclesiastical effect. The consequence of this complication of disorders is a church empty, in proportion to its size at least, and therefore cold and comfortless to the worshippers; whereas the same sum would have built two, or perhaps three churches, not so vast, but far more beautiful, accommodating a much larger aggregate of worshippers, and forming each a centre, far more satisfactory, for the exertion of a larger number of pastors. And this there can be no doubt would have been the happier result, had the public mind been imbued, by whatever means, with those principles of ecclesiastical taste and feeling in such matters, which it is the object of such societies as this to inculcate; had those who gave their best energies to the perfecting of so good a work, been prepared to think with good taste, good feeling, good judgment, and what is inseparable from these, real utility upon the subject.

In speaking of new churches, we have chosen those which were in every sense a public work, and the responsibility of which was so greatly divided between the several parties concerned in their erection and arrangement, that they are open, with as little invidiousness as possible, to free criticism, and that it would be impossible to lay blame any where, if blame is due, but on the deficiency of the public taste at the time, for which no individuals can be accountable. But though some of the very best churches lately built have been erected under the auspices of individuals, yet to whatever class of churches we turn we still find excellence, and even propriety, the exception; and are the more confirmed in the conviction that a little greater cultivation of ecclesiastical taste would tend to the erection of far more beautiful churches, without any addition of expense, and sometimes even at a material saving.

In the repairs of churches, to which we would next direct the attention of the Society, the same thing is equally true; as we shall abundantly prove by an enumeration of some of the more common errors into which the re-

pairs of churches are continually falling. We will again refer to actual instances though without mentioning names.

In a district of this county, the churches of which amply repay attention, there are two towns about ten miles apart, to which and to the several villages between which we will make an imaginary tour of observation.

The first church is a magnificent cross church, with a lofty spire, supported by flying buttresses, and must have been, when in its best state, among the most beautiful ecclesiastical structures in the kingdom. At present, the lower part of the great east window is blocked up by the painted canvas containing the creed, the Lord's prayer, and the ten commandments; the west window being equally spoiled by a gallery erected before it. The font, a very fine one, is not used for Holy Baptism, but only as a receptacle for a fair yellow wash-hand basin, which has usurped its use; the pewing is very irregular, and destructive of all effect; yet this is the least barbarised of all the churches we are visiting, and is indeed far less so than most others throughout the kingdom.

The next church is very small, and most unpretending, though containing some good monuments. It has a pretty screen between the nave and the chancel, which was very graceful in effect so long as it retained its original hue, but it is spoiled by white paint, and all its effect is destroyed by the emulous vicinity of the tall open panelling of a squire's pew.

The next church consists of a nave and two aisles, with a spire. The wooden roof has been lowered to so painful an excess, that the upper part of the east window is cut off by the new ceiling; the same window has also suffered the loss of a whole compartment, which is wantonly blocked up. Over the south door of the chancel is a stone with an inscription offensively commemorating a lord of the manor, who was probably art and part in some of these improvements.

The fourth church consists of a nave and clerestory, aisles and chancel, with a tower and spire. The roof of the nave is lowered, but it is still a pretty good oak roof. The tower arch is blocked up, and a gallery extends across it. The seats are arranged in the most originally fantastic manner possible, bending towards each other, like two marks of parenthesis, extending along the opposite sides of the nave. The font has lately served the purpose of a plasterer's bucket.

A little chapel, once very pretty, next occurs, but its effect is quite destroyed, both internally and externally, by a low square brick tower erected upon it, three sides of which have no other support than wooden props and beams. Perhaps by this time it has fallen, for the beams were very visibly and even alarmingly declining two years ago. If the tower has fallen without further damage, and has been replaced by a bell gable, which would cost a third part as much, the chapel is again a pretty ecclesiastical looking object.

Sixth and last, is the most beautiful edifice of all, a cross church, with a central tower, and splendid in all its parts, except where it has been barbarized at considerable expense by late improvers. The altar screen is of Grecian design. The roofs are lowered throughout the whole church, and those of the nave and south transepts are plastered. The west window is utterly spoiled, the nave is cut off from the transepts by galleries. The beautiful font is furnished, as almost all fonts are in these days, with a small basin for the water at Holy Baptism. The repairs on the exterior would have demanded so considerable an outlay, had they been really and wholly in keeping, that they could hardly be mentioned among things that would require only greater knowledge to have rendered them appropriate, but still they might have been less dissightly, to say the least, than they are, at the same cost.

In all these cases, such trifling matters as the glazing of windows and the like have been omitted, not as unimportant, but because they would have recurred so often as to be tedious.

It is not necessary to prove our point to give the names of the several churches we have visited, for every neighbourhood will furnish parallel cases, as each member of the Society may prove for himself on inspection.

Now, what we said of the "Million Churches," and of the divided responsibility of all persons concerned in the fabric, we repeat of such repairs. Had there been Architectural Societies in existence, or had the ecclesiastical taste been cultivated in any adequate degree, these things would have been different. More money would have been expended in fact, because devotional feeling would have been more stimulated in that direction; but this we will not assume: we will only assert that the same money would have been expended to very much better purpose.

To undo gradually and ultimately such evils as are here mentioned, and at the very least to prevent their so frequent repetition, is among the objects of this society, as well as to improve the character of churches newly erected. The field of usefulness (for surely such an object will be admitted to be useful) is co-extensive with the county, and every Yorkshireman will feel that it ought to be fairly cultivated. The means of effecting any good results may seem more limited, but the difficulty will vanish before a little consideration.

The first tangible operation of the society will probably be to obtain accurate information concerning the character and state of the churches of Yorkshire, and to collect and record whatever there may be curious and instructive in their architectural details; forming at the same time, as we may be able, a collection of casts and drawings, not from Yorkshire exclusively, but from any interesting source which may be open to us. Such a collection may seem only a museum of curious fragments, and the more extended pub-

lications of the Society mere barren records of what was once effected; and yet, even if the funds of the Society should not be adequate to any direct exertions, much will be effected by this means.

For the study of ecclesiastical architecture cannot be pursued without originating and fostering a degree of interest and enthusiasm which must be influential on the many, although it be called into active exertion only in a few. The very collection of information, with the examination of churches requisite to that end, will enlist many on the side of propriety and good taste, and there are many cases in which these appeal so intelligibly to common sense, and even to mere utility, that they have only to be fairly stated to be acted on. Every member, too, of this society will feel himself pledged, by the very fact of his membership, to exert himself in the furtherance of its objects; and at least when he has any voice and influence in the erection or repairs of a church, (and very few indeed of the clergy, at any rate, are wholly without such occasions of influence,) he will feel bound even at a little self-sacrifice, to care effectually for the appropriate character of the House of God. Nor ought we to refrain from the praise which is due in general to churchwardens and others who may be charged with the maintenance of the church's fabric. In rural districts they are generally chosen from among those whose very different pursuits leave them little opportunity for a personal acquaintance with ecclesiastical architecture and design; but good feeling they have to a great extent, and good sense; and when they find one, as for instance, the clergyman or squire of the parish, to direct them, they will seldom be found opposed to those measures which are really the best.

But we may surely anticipate the time when the funds at our disposal shall enable us to do something, as a society, in the way of restoration; and something, also, towards raising the architectural character of churches still to be erected. There are churches and chapels in this county diverted from their holy purposes, which we should wish, and which perhaps we may eventually be able, to rescue from secular and degrading uses. There are beautiful structures, with enough of them left to show what they once were, which we may hope gradually and one by one to restore. There are churches worthy of being imitated, which we may hold forth to the admiration of church builders, and the adoption of the plans of which we may procure by a seasonable addition to the building fund.

Meanwhile the members who may be really disposed to enter into what may be called the business of the society, will find it one of great interest, and will be amply repaid for their contributions to the society's museum and stock of knowledge, by the pleasure which the pursuit has afforded. The value of an object of interest in our rambles is proverbial, and hence a great part of the pleasure of the botanist, the mineralogist, and the painter. The student of ecclesiastical architecture is not less abundantly stored with interesting objects wherever he goes. With an interest attached to that particular object, and none other, every one, though but a wayfarer, with a few minutes' leisure, turns at once to the village church; but the members of our society will go thither with far greater assurance of pleasure and instruction, and stones will be vocal to him that are dumb to others. Every church has a history which may be read in its walls, its buttresses, its doors, its windows, its mouldings, its font, its roof, its seats, its chancel, its altar; a history with its eras, its incidents, and its episodes marked in broad lines, and in traces deep and vivid of the chisel of the mason and the sculptor, and of the brush of the plasterer and painter; in the restorations and additions of mediæval architects, and in the perversions and monstrosities of modern carpenters and masons. The history is one of interest and of value, and one which he can transcribe and bring away for the amusement and instruction of others, and not without a hope that he is acquiring and conveying information which will be practically applied in many future instances.

But let us attempt to convey some impression of the interest of the pursuit which we are entering upon, by a particular instance. Three years ago, two persons, now enrolled among the original members of the society, were walking on the banks of the river Ure, near Ripon, when their attention was arrested by what seemed in the distance a neglected ruin, but of what character, whether a church, a house, or a barn it would be difficult to say. However, they bent their steps towards it, and first approaching a cluster of almshouses, found the supposed ruin to be a little chapel, sadly neglected, and almost desecrated, by the near approach of houses, farm yards, pig sties, and every kind of rubbish. The exterior, besides being extremely picturesque, chiefly from the effect of a tall bell-gable, afforded indications of great antiquity, and of very considerable changes; and in short, bore upon its face the history of six hundred years. The door-way had been Norman, the East window was of three or four hundred years later date, and there were traces of intermediate alterations; while the present dilapidated state of the whole edifice, gave in sad colours the story of the last two or three centuries. Within, the little unpretending chapel was full of still deeper interest. The wooden roof, the original open seats, and the screen remained, though craving many repairs. Altar rails there were none, and never had been; before the altar was a little circle of mosaic, and the altar itself was such as was not then generally known to exist in the whole kingdom—it was the old stone altar, which had escaped the hands of sacrilege and destruction. Now this was, all will admit, an interesting discovery, and it was certainly more than will fall to the lot of every one every day; but it is so far from being unexampled, that day after day other stone altars are being discovered, and other churches and chapels which have been hitherto as little noticed as that of St. Mary Magdalene, Ripon, are found to contain the most

interesting remains, and details well worth the study of the student of practical ecclesiastical design.

Enough, perhaps more than enough, has been said, to conciliate your favour to this society, and to stimulate your interest in its pursuits. Here therefore, we should conclude; but it is perhaps as necessary to disarm suspicion, by stating the limits of this society's operations in one direction, as to say what we may well hope it really will effect. It will not, then, interfere with the strictly professional labours of the architect, nor in any respect supersede the application of his skill and science. On the contrary, it will afford him a very great support, unless we over estimate its influence on the public mind, against the injudicious suggestions and the very irritating interference of those who cannot be supposed really to understand the subject yet who stand greatly in the way of any degree of excellence in the works committed to their oversight. Those architects who really understand the principles of Gothic architecture and of ecclesiastical design, and who only want room and liberty, and a just appreciation of their talents to distinguish themselves, will, we are persuaded, find in the Yorkshire Architectural Society a very effective ally.

Having thus stated the object of the society, we may, we trust, leave it to the favour of the public, and at once, with the confidence of all parties, enter upon its pleasing and useful sphere of duties.

REVIEWS.

Appendix E, F to the new edition of Tredgold on the Steam Engine. Engines of the Trent and Isis, Dee and Solway, &c. Twenty-one Illustrations. London: John Weale, 1842.

THE chief fault we have to find with this work is that there is too little of it. Brevity, indeed, is a quality of which we rarely have to complain, yet in the case of such machinery as that of the *Trent* and *Isis*, we should rather have had all the details, though the work had been a little dearer and more voluminous in consequence. It forms no part of our function to inquire whether it is upon the publisher of the work or the makers of the engines, that the absence of these details is chargeable; but the policy which has withheld them, wherever it may have originated, is, we are satisfied, a blind and injudicious one, and is impotent for everything but mischief. The only drawings of these engines which are given, are a plan, elevation, and end view; and these, we suppose, are to prove their title to the public admiration:—as if any one could tell whether an engine were good or bad by merely looking at the outside of it. We are, it is true, provided with the performance of the engines as determined by the indicator; but every one knows that an indicator diagram furnishes no criterion of the quality of an engine as a piece of mechanism, and that an engine may give an admirable diagram, and yet be a bad engine in many respects. The true character of an engine is, it appears to us, only to be determined either by an examination of the details of its construction, or by the experience afforded by its prolonged operation. The latter test is certainly a very satisfactory one, but requires a lifetime for its application, and is, we fear, too tedious and transcendental to arrest very forcibly the public attention, or enable a man to make his way among a crowd of tumultuous competitors. Those who plume themselves upon mysteries unknown to the commonalty, and imagine that the public confidence is to be won by lofty and unsupported pretension, will be laughed at and disregarded, and we think that Messrs. Miller, by withholding from the public eye the details of their engines, have defrauded themselves of the glory to which they were justly entitled, and rendered vain the superiority which those details would have made manifest. However sensible we may be of the excellence of Messrs. Miller's machinery, we are as sensible that any praise of ours is open to the charge of partiality which is based upon evidence inaccessible to the public; and we are heartily provoked at a policy which renders our commendation fruitless, and casts a veil over such high and varied excellence.

It may, indeed, be the case, that the denial of these details to the public is only a peace offering to that passion for secrecy which has become epidemic among engineers, and which we look upon as one of the most humiliating events in the history of that great fraternity. But this is surely a very pusillanimous motive, and even on the score of expediency affords, we think, but a poor palliation. The sober part of the community very well know that any attempt at secrecy in engine making is preposterous, and that it is impossible to prevent people from becoming acquainted with the structure of engines which are scattered all over the world, and to which any one may obtain such easy access. Engravings of the best engines of Messrs. Maudslays and Messrs. Miller, in which all the details of construction are represented, are current enough on the Continent, and the French are

at this moment constructing engines from accurate drawings of those of the Great Western. The engines of one maker are frequently put into the hands of another for repair; draughtsmen and mechanics migrate from one factory to another, carrying with them all its mysteries, and every one knows that any particulars of any practice may be obtained without considerable trouble. Yet in the face of all this, each engineer imagines that he possesses certain mighty secrets which are hid from all the world beside, believes that the publication of a few very well known expedients would ruin him entirely, and mistakes the rejection by other engineers of the plans he has chosen to adopt, for a happy ignorance of their existence. Opinions, however, such as these, are only to be laughed at, but a different demeanour is due to those who not only refuse to give any practical information on the subject of the steam engine themselves, but throw every impediment in the way of those who are disposed to be more communicative. The appearance of Mr. Farey's admirable treatise on the steam engine was gall and wormwood to these high-minded gentry, because, indeed, "they feared it would make every body else as wise as themselves," and the publication of some of the dimensions of marine engines in a late number of this Journal raised a din and consternation which we could not have conceived possible from a cause so inadequate. For this and other aids to engineering we have been held up as enemies to engineers, and have been charged with the infliction of injury upon individual practitioners, by opening the door to the crowd of uninitiated. But upon what authority was the door ever closed, or when did it become insupportable injustice to hinder men from being unjust to their neighbours? There is but little of the knowledge which contemporaneous engineers possess, which they have not derived from their immediate predecessors, and in attempting to exclude the rising generation from the benefit of this common stock, they have arrogated to themselves a right they never could have possessed. Toleration for their personal prejudices and private aberrations we are willing to accord in the largest measure; but who ever heard of toleration for intolerance? Who ever heard a man cry out because he might not insult and tantalize his fellow creature, choke up his path with thorns, and shut him out from benefits to which he is equally entitled? Every one but the members of this party can see the folly and injustice of such courses, and those who have the interests of those persons most at heart, will be the most solicitous to wean them from them.

The first article of the letterpress which accompanies the plates is an account of the hulls of the *Trent* and *Isis*, which contains some acceptable information. The next article is a short account of the *Orion* steamer, and then follows a description of the engines of the *Isis*, which betrays, we fear, a little superficiality, yet contains much strong sense, and only a moderate infusion of error. After this comes the specification of the hull of the *Cyclops*, and lastly an account of the engines of the *Dee* and *Solway*. The few remarks we intend to indulge in we shall devote principally to the machinery of the *Trent* and *Isis*, by Messrs. Miller & Ravenhill, and that of the *Dee* and *Solway*, by Messrs. Scott & Sinclair, of Greenock.

The most conspicuous peculiarity of the engines of the *Trent* and *Isis* is the absence of all pretension to architectural beauty. The frames of the *Dee* and *Solway* are of the Gothic order, the crank shaft being supported by Gothic columns. In the *Trent* and *Isis* on the contrary, the crank shaft is sustained by unadorned plates of metal, with large feathers cast on their sides to stiffen them laterally, so that the section of each support somewhat resembles the figure of a double cross. The purpose of this practice is to distribute the metal properly in every part of the frame. In the case of columns, it is contended, the core may float in the process of casting, and make the column thicker on the one side than on the other—a defect to which the crucial system is not liable, but the existence of such a defect at all, involves the supposition of excessive negligence on the part of the moulder, and is altogether so remote and unusual as to be only susceptible of measurement by an infinitesimal mensuration. If pipes can be cast without any injurious inequality when the thickness does not exceed half an inch altogether, it is difficult to see how the injury can be very serious when the thickness is increased to 3 or 4 inches, and the proportion of any inequality diminished correspondingly.

The author of the description of these engines ascribes great importance to the horizontal crosses introduced in the *Trent* and *Isis* between the crank and intermediate frames of each engine, but we dissent from his judgment in this particular, and attach far more importance to a horizontal cross between the engines. He wastes much rhetoric in showing that the shock of the paddles and the racking which ensues when the engine is reversed constitute strains which it is hard for the framing to resist. But the formidable character of these strains is as regards the framing purely imaginary, and the

whole of this part of the description, though indicating considerable talents, is overcharged, hypothetical, and preposterous.

The diameter of the cylinder of the *Isis* is 74½ in., the length of the stroke 7 ft., and the number of strokes per minute 11½; the mean vacuum in the cylinder 12·705 lb.; the mean steam pressure 2·235 lb., which deducting 1·25 for friction, leaves the effective pressure on the piston 13·69 lb. per square inch. The indicator diagram shows the steam to be cut off at between two-thirds and three-fourths of the stroke. The quantity of lap proper to this degree of expansion may be computed by a formula we gave in a former number.

The *Isis* was, we understand, a very heavy vessel, sank deep in the water, and was in consequence never very rapid. The author of the description before us, suggests, that inasmuch as there would appear to be an objection against working large engines at a high speed, it might be expedient to employ small engines in steam vessels, and work them at such a speed as to produce a power equal to that of the larger engines working slowly. But there is nothing to prevent large engines from being worked at a high speed so far as the engines themselves are concerned; and the speed of the engines of the *Isis* might easily have been doubled without difficulty or detriment. But if the engines of a steam vessel be worked at such a speed as to involve the rotation of the paddle wheel with undue rapidity, a large proportion of the engine power will be wasted in throwing the water back from the wheel instead of being spent in forcing forward the vessel. In short, a certain relation must always subsist between the velocity of the wheels' rotation, and that of the vessel's progress; and this must of course fix the velocity of piston which in a vessel of ordinary construction will produce a maximum effect. Small engines driven at a high velocity might answer very well if the paddles were on the second motion, as it is technically phrased; in other words, if they were so arranged that the engines might run at a high velocity without affecting the relative speeds of the paddles and ship; but with the present modes of arrangement, small engines would not answer at all; and we do not see how it is possible to apply them under any sort of arrangement, without resorting to cog wheels, which in steam vessels are, it is agreed, objectionable.

We have never been any great admirers of the engines of Messrs. Scott and Sinclair, yet in many points we admire the engines of the *Dee* and *Solway*. They are greatly superior to anything we have hitherto seen from the same factory, and are we think a favourable specimen of engines of Clyde manufacture. There remains, it is true, even yet a good deal too much of the old leaven; the joints, for example, are still made of rust, instead of being metal to metal, as in the London engines; the air pump rods are cased, and the iron is exposed to the corrosion of the salt water at the lower ends, instead of which they ought to be of solid copper or Muntz's metal; the valve casings are without expansion joints, the effect of which must be to keep the joints on the level of the cylinder cover in a state of eternal leakage; the piston packing consists of three tiers of rings, and is of an antique and complicated description, long exploded in civilized communities; the upper and under portions of the D valves are connected by two rods instead of three, and the holding down bolts are of the most perishable description; yet in spite of these defects, the engines are upon the whole of excellent quality, and contain, perhaps, more excellences and fewer imperfections than are to be found in the works of some makers of more exalted pretensions. The framing, we look upon as being the handsomest, and among the best of any hitherto constructed; the side levers and many of the other working parts are well proportioned, and there is manifestly no niggardliness either in workmanship or materials. Whatever faults may still adhere to machinery of this firm, they are not, we conceive, attributable to penury of skill, or insensibility to excellence, but arise, we think, from the difficulty of changing completely and suddenly a vicious system. Most of the grosser vices have already been extirpated, and the whole may be got rid of in a few years time, even at the same rate of progression.

We have, we fear, drawn out these remarks to a greater length than our readers will thank us for, and have only room to observe in reference to the drawings of hulls of vessels here given, that they are excellent. This part of the work contains a large fund of valuable information, and will, we are sure, be appreciated by a wide circle of readers. The whole of the plates are admirably engraved, and the typography which accompanies them is of the very first quality; nothing, indeed, can surpass the skill and liberality which shine out in the mechanical department of all the works issued by this publisher; and the height of this very excellence makes us the more regret that the intellectual department is so rarely of a correspondent quality.

Blunt's Civil Engineer and Practical Machinist. By CHARLES JOHN BLUNT, C. E., &c. London: Ackerman and Co.

To describe the contents of this work is the best way to show its value. They consist of six copper-plate engravings the size of imperial, taken from the working drawings from which the machines were actually made, which renders them authentic records of the machinery of some of our first engineers. We could have wished, however, to have seen a little more finish to some of the plates, and the dimensions more generally given; for instance, we will allude to the engraving of the Thames Tunnel, in which the inverts appear to abut upon nothing in the centre, and the brickwork of the shaft ought to have been shaded or hatched.

The first plate contains the drawings of a marine dredging and excavating engine, and deepening machine, employed in the formation of harbours, constructed by Messrs. Rennie, being the engine erected for the harbour of Barcelona; the plate is 42 in. long, and 18 in. broad; many of the details are delineated upon an enlarged scale. Mr. Blunt contends, that the late John Rennie was the original inventor of the dredging machine, but does not state the year he first introduced it at the Hull Docks. This statement is at direct variance with an article that appeared in the *Journal* for January 1839, page 9, vol. 11, by Mr. Thomas Hughes, wherein he claims the invention as that of his father, who used the dredging machine off Woolwich, in 1804. Now the question is, did Mr. Rennie introduce the machine prior or subsequently to that date? Mr. Hughes says subsequently, which remains to be disproved by date. There cannot, however, be a question that the late Mr. Rennie, together with his talented sons, have brought the machine to that great perfection it has now attained.

The second and third plates represent a steam engine for driving machinery and mills by Messrs. Rennie. The fourth contains drawings of a direct action marine engine, with side guides, and the section of an iron steamer, also by Messrs. Rennie; we have here to find the same fault as we have done in another review given in the present *Journal*, for omitting to give the sections showing the interior of the engines, and likewise some details and dimensions; without them, it is useless to give mere views of the exterior. We believe this vessel and engines were tried by Messrs. Rennie during the last season, when the vessel proved to be one of the fastest steamers on the river Thames. The fifth plate is the Thames Tunnel, containing a longitudinal section, showing the archway, the shield, the driftway, and the formation and sinking of the large shaft on the Middlesex side of the river. The sixth plate is devoted to a fifteen ton crane, constructed by Messrs. Rennie.

We think we have shown enough of the work to prove its importance as a national record, and a work of value to the engineer. We trust, however, that in future more attention will be paid to the engravings, and likewise to the insertion of the details, which will greatly enhance the value of the work, and make it one of reference for the profession.

The Mechanical Principles of Engineering and Architecture. By the Rev. HENRY MOSELEY, M.A., F.R.S., Prof. of Nat. Phil. in King's College, London. London: Longman & Co., 1843.

Professor Moseley's previous works have at various times come under our notice, and we have felt it our duty to express our feelings of the spirit of research and enterprise with which the author has exerted himself for the promotion of constructive science. Placed at the head of an important department of collegiate instruction, Mr. Moseley has felt the necessity that exists for the adaptation of scientific principles to the practical pursuits of the engineer and architect, with whom the progress of new combinations and new constructions renders it imperative that the classbooks and works of reference should be frequently remoulded and made applicable to the wants of the day. It is in union with these requirements that Mr. Moseley has been induced to undertake this work, in which the application of mechanics in the varied pursuits of the engineer and architect is taken into consideration. Under the head of dynamics, Mr. Moseley has directed his attention to the subject of *duty*, for which he proposes to substitute the term *work*, in imitation of the French '*travail*'; he observes, that "the English word '*work*' is the obvious translation of '*travail*,' and the use of it appears to be recommended by the same considerations. The work of overcoming a pressure of one pound through a space of one foot has in this country been taken as the unit, in terms of which any other amount of work is estimated; and in France the work of overcoming a pressure of one kilogramme through a space of one metre. M. Dupin has proposed the application of the term *dynamie* to this unit.

I have gladly sheltered myself from the charge of having contributed to increase the vocabulary of scientific words by assuming the obvious term '*unit of work*' to represent concisely and conveniently enough the idea which is attached to it, without translation." To the term "*unit of work*," we cannot see any objection.

Mr. Moseley's researches on the mathematical relation of machinery, which he terms "*the modulus*," are known to our readers; in the present work he has applied himself to the determination of the modulus of toothed wheels, and of bevil wheels, and he has also considered the influence of the friction of the teeth of wheels and that of their axes and weights. Upon this he observes, "an approximate form of this modulus applies to any shape of the teeth under which they may be made to work correctly; and when in this approximate form of the modulus the terms which represent the influence of the friction of the axis and the weight of the wheel are neglected, it resolves itself into a well known theorem of M. Poncelet, reproduced by M. Navier and the Rev. Dr. Whewell. In respect to wheels having epicycloidal and involute teeth, the modulus assumes a character of mathematical exactitude and precision, and at once establishes the conclusion (so often disputed) that the loss of power is greater before the teeth pass the line of centres than at *corresponding points* afterwards; that the contact should, nevertheless, in all cases take place partly before and partly after the line of centres has been passed. In the case of involute teeth, the proportion in which the arc of contact should thus be divided by the line of centres is determined by a simple formula; as also are the best dimensions of the base of the involute, with a view to the most perfect economy of power in the working of the wheels." In the third part our author has taken up a subject, but little treated upon in works of this nature, hitherto. The theory of machines, in which he considers the simple powers and their applications, the capstan, the Chinese capstan, the whingin, the applications of the screw, the beam of the steam engine, the crank, double crank, crank guide, governor, carriage wheel, &c. The fourth part is devoted mainly to construction, and in this are carried out and applied Mr. Moseley's researches on the line of resistance as occurring in walls, foundations, buttresses, piers, &c. In the discussion of the distance of the line of resistance from the extrados of a structure, at the point where it most nearly approaches it, Mr. Moseley has called it the modulus of stability, preferring this measure of stability to the co-efficient of stability used by the French writers. In the determination of the pressure of earth upon revetment wall, and in the theory of foundations, Mr. Moseley has introduced to English students, M. Poncelet's application of Coulomb's theory. Mr. Moseley's views upon the theory of the arch, are known to the public, by his contributions to Hosking and Hanu's "*Treatise on Bridges*;" and in the present work he has inserted the tables of the thrust of circular arches, calculated by M. Garidel, from formulæ founded on the theory of Coulomb. In considering the strength of materials, Mr. Moseley has applied a new method to the determination of the deflexion of a beam under given pressures, and under this head as incidental to the discussion of rupture by elongation, the theory of suspension bridges has been considered. Upon this he says, "This question, so complicated when reference is had to the weight of the roadway and the weights of the suspending rods, and when the suspending chains are assumed to be of uniform thickness, becomes comparatively easy when the section of the chain is assumed so as to vary its dimensions as to be everywhere of the same strength. A suspension bridge thus constructed is obviously that which, being of a given strength, can be constructed with the least quantity of materials; or, which is of the greatest strength having a given quantity of materials used in its construction." A new class of problems has also been introduced by the author, having reference to the forms of girders connected by slender ribs or by open framework. The subject of the strength of breastsummers has also been extensively investigated. There are several tables dispersed throughout the work and in the appendix which are of great use both to the engineer and architect. We are much gratified with this work indeed; the more so, as the author has availed himself successfully of the labours of the French mathematicians, whose superiority is not merely unrivalled, but almost unknown in England. The best, therefore, that we can do at present, is to profit by their exertions, with the hope that when once we enter into the field, we may, as in other cases, ultimately take the lead where our neighbours have shown the way. The work of Professor Moseley may indeed be considered as an earnest of what may be done in "*applied mechanics*," hitherto so much neglected by us, although of such essential importance. This is a good beginning, but we hope to see the subject carried out in practical examples, so as to be within the reach of the working man.

The Cornish, and Boulton and Watt Engines, erected at the East London Water Works, Old Ford. THOMAS WICKSTEED, Engineer. London: John Weale, 1842.

Mr. Wicksteed has been unceasing for the last five years, in bringing forward the merits and the superiority of the Cornish engine, for pumping; he has manfully fought through all the prejudices that were raised up against it. Before the Institution of Civil Engineers, has he night after night contended, almost single handed, with his opponents; in the engine room has he daily watched the progress of the construction of the engine, and hourly has he experimented upon every part of the ponderous machine, to trace the cause of the superiority of the Cornish engine for pumping, over that of the ordinary engine; all his experiments he has recorded publicly, in such a plain, candid and unostentatious manner, that it has called forth the praise of all; these were published some time since, and reviewed by us in the *Journal*, p. 398, vol. 4. Now, he has given us the engine itself, so accurately set forth in plan, section, elevation, detail and dimensions, without attempting to conceal any portion, so that any engineer may set to work and construct an engine from the drawings he has favoured us with. Besides the Cornish engine, Mr. Wicksteed has also furnished us with drawings and description of the Boulton and Watt Pumping Engine and Boiler, upon which he also made the experiments before alluded to. The plates are elaborately engraved by Gladwin, of the size of imperial, and are accompanied with a very clear description, drawn up by Mr. Graham, the Secretary of the Society of Arts. There are four plates of the Cornish engine and boilers, and four plates of the Boulton and Watt engine and boilers, which likewise exhibit Stanley's Feeding Apparatus; and with the letter-press there is an engraving by Lowry, of Messrs. Harvey and West's Patent Pump Valve, similar to the one with description that was inserted in the *Journal* for February 1840, vol. 3, p. 41. These valves ought to be adopted for all large pumping engines.

We are sure it is unnecessary for us to recommend such a very valuable work to the profession, for we feel certain it will soon be in the hands of every one who takes a lively interest in the steam engine.

Companion to the Almanac for 1843.

OF this new volume of the "Companion" we shall say very little at present, it being our intention to notice the architectural subjects it contains next month, when we shall be able to speak of them more fully than we can now do off-hand, just as our number is going to press. In the interim we merely mention some of the articles in the bill of fare, viz. Messrs. Wyatt & Brandon's new church at Wilton, and their Assize Courts at Cambridge; Mr. Poynter's church, Broadway, Westminster; the Wesleyan College or Institution, Richmond; and Mr. Ewart's offices, Liverpool; which last structure is not the least commendable for the taste displayed in it. Although these constitute the more prominent subjects, several other buildings are noticed, and some of them are rather fully described—for instance, the houses composing the façade and building in front of Marks' Carriage Repository, Langham Place, or rather what is the principal one of that group of houses, and which, though it does not show itself externally to be larger than the rest, is internally equal to three of them. This residence is laid out in very superior style, and has a library or gallery very striking in its plan and effect.

There can be no doubt that the "Companion" has contributed not a little to render the subject of architecture more popular than it used to be, as it is a very widely diffused publication; nevertheless, that portion of the work is susceptible of improvement, for a greater number of pages might be allowed for it.

Philosophical Conversations. By FREDERIC C. BAKWELL. London: Harvey and Darton.

This is the second edition of a cheap and popular work on the application of natural philosophy to the pursuits of daily life, and is an explanation of the most striking terrestrial phenomena, and which we strongly recommend to the young friends of our readers.

Ancient and Modern Architecture. Edited by M. JULES GAILHABAUD. Part 2. London: Didot & Co.

The present number is of more interest even than its predecessor. It introduces to the architect the Persian monument of Nakshi Rostam, a most curious specimen of that ancient school of art. The accompanying plates illustrate the well known cave temple of Ellora, in the East Indies.

Record of Patent Intentions. By ALEXANDER PRINCE.

A valuable addition to this class of periodicals. It takes upon itself as its distinguishing characteristic, the duty of giving *all* specifications as they are enrolled, which appears to be done with great clearness.

Adcock's Engineer's Pocket Book for 1843. London: Simpkin and Marshall.

This contains the usual mass of valuable tables and useful information for the engineer.

English Patents. By ANDREW PRITCHARD. London: Whittaker and Co.

This is a useful list of patents for 1841, with an index.

PROF. DONALDSON'S LECTURES ON ARCHITECTURE.

We have on several occasions attended Mr. Donaldson's courses at University College, and are pleased to see the success that attends him in the discharge of his duties, and in the number of his pupils. The courses at present are purely elementary, and are well illustrated with drawings and experiments. From time to time examinations of the pupils on the previous lectures take place, when the pupils answer either orally or by drawing the subject to be described. It was evident from these examinations that the class possesses the best qualifications in students—attention, and they seem also to take a great interest in the lectures. In a recent lecture on the Corinthian order, Mr. Donaldson observed, in reference to the fabulous origin of the capital, that some people were inclined to look with a severe eye on such tales. He, however, did not think that in a study so abstruse as theirs, the imaginative should be quite discarded. He thought that they ought to be allowed to beguile themselves a little in the regions of imagination. Paraphrasing Cicero's saying—"Nemo unquam magnus fuit sine aliquo afflatu divino," he went on to remark that, "no man ever produced a great work without great effort of their imagination; and that if they rejected the fable on historical grounds, they could at least learn one lesson from it—always to look at nature, and they might derive from the commonest objects happy ideas which they might introduce into their own works. Even going along in his walks in the neighbourhood of the metropolis, he often saw in the rank weeds of the ditches, luxuriant foliage, well calculated for architectural effect, and took out his pencil and sketched them." He gave it as his opinion that the original Corinthian capital was to be sought in those specimens where the corniculi are deficient and where only a row or two of foliage surrounds the cap.

WHITE LEAD.

A new process of manufacturing white lead or carbonate of lead, (and for which a patent has been granted for Great Britain and Ireland,) is now being exhibited at the late "Pin Manufactory," in the Borough Road, Southwark. We have not yet had an opportunity of fully satisfying ourselves as to the white lead produced by it, and shall therefore notice it in our next number. However, as far as we can judge from examining some small samples which have been furnished us, we are of opinion that the quality is quite equal to the best made by the ordinary or old process. The rapidity, cheapness, and simplicity with which the metallic lead is converted into a carbonate by this process, is sufficient to recommend it to the investigation of those who are engaged in the manufacture of so important and indispensable an article. We are informed that a manufactory, by the process alluded to above, has been for 2 years successfully in operation in America, and that patents have been secured in most of the Continental kingdoms.

South Eastern Railway.—The Saltwood Tunnel.—This work which has hitherto assumed a very formidable aspect owing to the immense quantity of water, we are happy to state is being successfully dealt with; the stratum is the lower green sand, containing an immense volume of water; the difficulty has been in sinking the shafts and driving the adits at the level of the bottom of the tunnel, which arose from the rapid collecting of the water so as to compel the miners to retreat from the works or they would have been drowned; this has now been successfully overcome, and the adit is torned completely through the hill so as to let all the water run out at one end, where nearly 30,000 gallons of water now flow every hour; we are informed that about 30 millions of gallons of water were drawn to the surface. During the time the workmen drew 3500 yards of earth or about 30 times the weight of water compared with the earth. The tunnel is now commenced and there appears to be no real difficulty left in the way of its completion.

AINSLIE'S PATENT BRICK AND TILE MACHINE.

This Machine is now being exhibited at the "Pin Manufactory," in the Borough Road, Southwark; it is applicable for making Tiles of different sizes, and likewise Bricks of almost any shape, by simply shifting the front plate of the lower box. It is altogether different from any other machine that has hitherto come before the public. The articles made by it are of the best description, as the clay is in no way strained (as in some other machines, by turning the clay from a flat to a curve) but is in fact pressed through the moulds in an equal and regular manner, leaving the top as well as the bottom of the tiles, equally solid, substantial, and far more durable, requiring less fuel to burn them than in the ordinary mode of manufacture. One of the machines has been erected for the Marquis of Loughan, and appears from the following extract to answer the purpose.—"Amongst the machines recently introduced for the manufacture of drain-tiles, that under the patent of Mr. Ainslie, Redheugh, Mid-Lothian, stands pre-eminent, whether as regards the amount of its production, or for the quality of the article which it produces. There is a directness in the principle on which tiles and bricks are formed by this machine, that gives them at once greater solidity and soundness of texture than any process hitherto adopted. Tiles of any size, from a 9 in. main-drain down to the smallest conduit, can be made by this machine, at rates varying from 14 large mains to 36 small conduit-tiles per minute, or from 8000 to 20,000 per day."—*Stephens' Book of the Farm*, No. 7, p. 581, 582.

The following description of the machine, furnished by the ingenious inventor, will explain its action and utility.

In consequence of the rollers being near to each other, little more than one quarter of an inch apart, every obstacle, such as stones and other hard substances, are crushed to powder, in their progress downward, thereby giving proprietors of clay fields the power of manufacturing their own tiles, even though the clay should be of an inferior quality.

Immediately below the centre of the rollers is placed a cylinder lying horizontally, with an opening 1½ in. wide on the top, through which the clay enters; and on each side of the opening is placed a scraper to clean the rollers and duct the clay into the lower cylinder. In the latter cylinder there is a powerful double spiral screw which revolves, the threads are about 7 in.

apart, consequently whilst the rollers force the clay in a perpendicular direction through the opening into the threads of the screw, the screw forces the clay horizontally into the chamber in front of it. For holding the mass of clay into which the screw empties itself. In front of this chamber, a plate with moulds is screwed, so that when the chamber is charged, the overplus is forced through the moulds from the mass of clay in a continuous stream, on to an endless cloth, which moves the moulded clay forward to the cutting frame, consisting of two endless chains inclining a little from the perpendicular, to which, two wires are attached horizontally by hooks; these chains are moved by a belt to the shaft of the first roller of the endless web, to suit the speed of the clay, and is kept constantly revolving, so that the wires divide the clay, during the continuous movement of the new moulded tiles, which are then pushed forward by the uncut clay over small rollers, till they reach another endless web, from which they are taken.

In order to prevent breakages, a strong friction hoop is placed upon the driving shaft of the machine, which is screwed up, till it puts the machine in motion. Suppose either by accident or intention, iron or any other hard substance was thrust into the machine, this friction hoop will yield to the strain of such a substance, thereby causing the machine to stand still, till the obstacle is removed. When the clay is very irregular, a pug mill is recommended to feed the machine.

GILLOT'S PATENT FOR HEATING AND VENTILATING.

Fig. 1.

Fig. 2.

A. The Stove. The door of the fire-place opens on the opposite side. B. the Box containing the Fan. C. The Pulley on the spindle to which the fan is attached, over which passes a strap leading to D. the Fly Wheel, the turning of which sets the fan in motion, and drives the air through the cockle, Fig. 2, placed at G G, Fig. 1. and the air is carried through E, the delivering pipe to any part required. F. The chimney either ascending or descending.

This apparatus for heating and ventilating, may be seen in use at No. 1, Liverpool-street, Finsbury. The fire-place is similar in construction to ordinary hot air stoves, over which is placed a cockle, see Fig. 2, through the vertical spaces. A A. in which the fire passes, and the air, by the revolving of the fans, is driven through the intermediate spaces, B B, into the delivering

pipe, E, Fig. 1. The purity and quantity of the heat produced by this apparatus, must be witnessed to be believed; the air is driven with such velocity through the cockle, that the oxygen is not destroyed, as is the case, more or less, in all self-acting hot air stoves. The quantity of heat to be obtained is limited only by the size of the apparatus used, and the number of revolutions of the fan; any building, however large, can easily and speedily be warmed; in fact, this apparatus is capable of effecting all that can be desired for warming churches, all large public buildings, drying corn, new buildings, and manufactories of all kinds, where heat, with perfect safety and economy is required. It is not necessary that the apparatus should be upon the premises, but the heat may be conveyed into any factory or building, by trunks or pipes.

PATENT STUCCO PAINT CEMENT.

In a former number we slightly alluded to this new cement, deferring until we had an opportunity of examining into its qualities, to recommend it to the notice of the profession, which we are now enabled to do, after having carefully investigated its properties, and examined several samples of the cement, at Messrs. Mann's, Maiden-lane, in the City. It appears to be a cement possessing superior qualities, and to be well adapted for external works, particularly in exposed and damp situations, such as on the sea coast, and south-western aspects. At Plymouth, where the cement is manufactured by Messrs. Johns, the patentees, and where the principal ingredient is obtained, it has been tried for the last three years, and subjected to the most rigid tests with perfect success. Its strong adhesive properties cause it to adhere to almost any substance; specimens may be seen on glass, wood, slate, tile, and brick. The nature of the materials of which the cement is composed, renders it highly repellant of water, and impervious to wet or damp. It is sold in a semi-liquid state, which has the appearance of white lead; and when used it is mixed with three times its weight of sharp sand, to the consistency of mortar, and laid on the wall with a trowel in the same manner as cement, and with about the same labour. It is finished off at once, with either a fine or a coarse coat, as may be desired; it dries gradually, and in two or three days time the surface becomes as hard as stone, to which it has all the appearance, without colouring. It may likewise be used for interiors, and painted over

within a few days, a couple of coats being sufficient to cover it, as the cement is not of that absorbent character as stucco or roman cement.

The cost of the fluid cement is 14s. per cwt., and for covering a yard superficial of brick-work, it requires 7 lbs. of cement, and 21 lbs. of sand, or 4 lbs. of cement, and 12 lbs. of sand, if laid on a coat of plastering, or 1 cwt. of cement will take one bushel of sand, and cover 14 yards. The prime cost, including labour, is about 1s. 6d. per square yard, which is a low price, considering the excellent qualities of the material, and that it does not require colouring. We strongly recommend the architect to give the cement a fair trial. Some specimens may be seen at the office of the Journal.

THE ARTESIAN WELL AT GRENELLE, PARIS.

We have at various times given an account of this well, the first description of the labours of M. Mulot, up to the time of his accomplishing the objects in obtaining water, appeared in the *Journal* for April 1841, p. 131, vol. 4; and in the *Journal* for the following July, we gave a farther account, explaining the size of the tubes, and the geological character of the strata through which the boring passed. All the reports that have recently appeared in different publications nearly correspond with our reports, and the engraving lately published in Paris, showing the strata does not differ much from our description, but it gives the strata more minutely, which we now give in a tabular form. It will be perceived that the formation is identical with that of the London Basin below the London Clay.

Depth in ft.	STRATA.	Formation.
13.	Gravel and Sand	
	Cockle Shells	
	Quartose Sand with fine particles of sulphuret of iron	
	Fine Sand	Plastic Clay.

	Blue argillaceous and sandy chalk, with particles of mica, and veins of green chalk	
1634.	Clay with iron pyrites, nodules of the phosphate of lime and fossil debris	
	Green Sand	Gault.
	Clay and Greenish Sand with grains of quartz	
	Argillaceous Sand	
	Green and White Sand	
1794.	Water	

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM NOVEMBER 2ND TO NOVEMBER 17TH, 1842.

Six Months allowed for Enrolment, unless otherwise expressed.

MATTHEW GREGSON, of Toxteth Park, Liverpool, esquire, for "improvements applicable to the sawing or cutting of veneers. (A communication.)—Sealed November 2.

JOSEPH EDWARDS, of Bloomsbury-square, clerk, for "an improved razor-strop, or instrument for sharpening certain cutting edges, and an improved material for covering the same, which material is also applicable to other purposes."—Nov. 2.

SIR J. SCOTT LILLIE, of Chelsea, for "improvements in roads."—Nov. 2.

PIERRE PELLITAN, of Bedford-square, esquire, for "improvements in the production of light."—Nov. 2.

JAMES BULLOUGH, of Blackburn, overlooker, for "improvements in the construction of looms for weaving." (A communication.)—Nov. 3.

RICHARD BRYAN, of Liverpool, wine-merchant, for "arrangements connected with the circulation of steam employed in pipes or tubes for producing heat, and the application of such arrangements to various purposes."—Nov. 5.

JOHN ROTHWELL, of Great Bolton, grocer, for "a composition and prepara-

tion to promote the ignition and combustion of coke, coal, and other combustible substances, in stoves, furnaces, and grates."—Nov. 5.

WILLIAM COLEY JONES, of Vauxhall-walk, Lambeth, practical chemist, for "improvements in treating or operating upon a certain unctuous substance, in order to obtain products therefrom for the manufacture of candles, and other purposes."—Nov. 8.

PIERRE FRÉDÉRIC INGOLD, of Buckingham-place, Hanover-square, watch-maker, for "improvements in machinery for making parts of watches and other time-keepers."—Nov. 8.

ARTHUR HARVEY, of Wilmington-square, gentleman, for "improvements in the process of vinous fermentation." (A communication.)—Nov. 8.

THOMAS WRIGLEY, of Bridge Hall, Bury, Lancaster, paper manufacturer, for "improvements in machinery for manufacturing paper."—Nov. 8.

JOHN MITCHELL, of Birmingham, steel pen manufacturer, for "an improvement in the manufacture of metallic pens, and an improvement in the manufacture of pen-holders."—Nov. 8.

JOHN SINKS, the younger, of John-street, Bedford-row, gentleman, for "an improved apparatus for giving elasticity to certain parts of railway and other carriages requiring the same."—Nov. 8.

HENRIK ZANDER, of North-street, Sloane-street, engineer, for "improvements in steam-engine boilers and furnaces, and in the methods of feeding and working the same; as also in the machinery for applying steam power to propelling purposes."—Nov. 8.

JOHN BARNES, of Church, Lancashire, manufacturing chemist, and John Mercer, of Oakenshaw, Lancashire, calico printer, for "improvements in the manufacture of articles used in printing and dyeing cotton, silk, woollen, and other fabrics."—Nov. 10.

CHARLES ROWLEY and JAMES TURNER, of Birmingham, button-makers, for "improvements in the manufacture of perforated metal buttons."—Nov. 15.

ANDRÉ EUSTACHE GRATIEN AUGUSTE MACRASS, of Cornhill, gentleman, for "improvements in the process and apparatus for filtering water and other liquids." (Partly a communication.)—Nov. 15.

CHARLES SMITH, of Newcastle-street, Strand, for "improvements in the manufacture and application of bricks, tiles, and other plastic articles or surfaces, and for cements or compositions to be used with, in, and about the same, for building and other useful purposes."—Nov. 17.

MISCELLANEA.

The Cormorant Steam Frigate.—On the 23rd ultimo Her Majesty's second class steam frigate *Cormorant*, having been fitted with a pair of engines of 300 H.P., by Messrs. Fairbairn and Co., was tried down the river from Woolwich, under the charge of one of the Admiralty pilots. This was the first trip made by the *Cormorant*, and the government engineers on board were so fully satisfied with the working of the engines and the results obtained from them, that they at once ordered her to proceed to Sheerness, where she will be got ready immediately to be put in commission. The diameter of the cylinders is 63½ in., and the length of the stroke 5 ft. 3 in. The average number of strokes during the trial was 21½, the boilers generating an ample supply of steam. The draught of water of the vessel was 12 ft. 2 in. aft, and 10 ft. 3½ in. forward, the guns and armament not being yet on board. The speed through still water, according to the trials made at the measured distance, was 11 miles an hour; but greater speed will be attained when the paddle wheels have more hold of the water. The same makers are now constructing a pair of engines of 470 H.P. for Her Majesty's first class frigate *Vulture*, building at Pembroke. In the *Journal* for next month we hope to be able to give the drawings of these engines.

Aberystwyth Harbour.—The works of the pier are left closed for this season (excepting a few jobs). There is now completed of the new pier, 261 lineal yards, leaving only 39 yards for completion. The body of the work is composed of stone, from 1 to 14 tons, in rough blocks, and filled in with rubble stone. The sea slope is pitched, and grouted, with the best Aberthaw lime mortar; and a quantity of large blocks of stone are placed at foot of sea slopes, for its protection. The inner walling is composed of very heavy stones, set and grouted with the same mortar. The parapet wall is 8 ft. above the top of the pier, and of immense thickness. The stones forming its coping, weigh from 4 to 11 tons each, and are also grouted and set with the same mortar. The height of pier is about 32 ft., from foundation to top of coping, being 12 ft. above ordinary spring tides: the width on top 40 ft. the sea slope has an inclination of 3 to 1. There is also fixed a powerful capstan and mooring posts; landing steps are built in the inner walling. A convenient storm room is also erected in the parapet, for ropes, &c., for use of vessels. The pier as far as is completed, has been the means of saving life, and an immense quantity of property; as well as the facilitating of vessels, in their ingress and egress.

THE VARIATION OF THE COMPASS.

Observations made at the Royal Observatory, Greenwich,

G. B. AIRY, Astronomer Royal.

Mean Magnetic Declination for the month of August, 1842—23° 15' 10"

The observations of the Magnetic Dip are suspended, when they are resumed the results will be recorded as usual.
